

The Checker Framework Manual: Custom pluggable types for Java

<https://checkerframework.org/>

Version 3.4.0 (3 May 2020)

For the impatient: Section 1.3 (page 14) describes how to **install and use** pluggable type-checkers.

Contents

1	Introduction	13
1.1	How to read this manual	14
1.2	How it works: Pluggable types	14
1.3	Installation	14
1.4	Example use: detecting a null pointer bug	15
2	Using a checker	16
2.1	Where to write type annotations	16
2.2	Running a checker	17
2.2.1	Using annotated libraries	17
2.2.2	Summary of command-line options	18
2.2.3	Checker auto-discovery	20
2.2.4	Shorthand for built-in checkers	21
2.3	What the checker guarantees	21
2.4	Tips about writing annotations	22
2.4.1	Write annotations before you run a checker	22
2.4.2	How to get started annotating legacy code	22
2.4.3	Annotations indicate non-exceptional behavior	23
2.4.4	Subclasses must respect superclass annotations	24
2.4.5	What to do if a checker issues a warning about your code	25
3	Nullness Checker	27
3.1	What the Nullness Checker checks	27
3.1.1	Nullness Checker optional warnings	28
3.2	Nullness annotations	28
3.2.1	Nullness qualifiers	28
3.2.2	Nullness method annotations	29
3.2.3	Initialization qualifiers	29
3.2.4	Map key qualifiers	29
3.3	Writing nullness annotations	30
3.3.1	Implicit qualifiers	30
3.3.2	Default annotation	30
3.3.3	Conditional nullness	30
3.3.4	Nullness and array initialization	31
3.3.5	Nullness and conversions from collections to arrays	31
3.3.6	Run-time checks for nullness	32
3.3.7	Additional details	32
3.3.8	Inference of <code>@NonNull</code> and <code>@Nullable</code> annotations	32
3.4	Suppressing nullness warnings	32
3.4.1	Suppressing warnings with assertions and method calls	33

3.4.2	Null arguments to collection classes	33
3.5	Examples	34
3.5.1	Tiny examples	34
3.5.2	Example annotated source code	34
3.6	Tips for getting started	34
3.7	Other tools for nullness checking	35
3.7.1	Which tool is right for you?	35
3.7.2	Incompatibility note about FindBugs @Nullable	37
3.7.3	Relationship to Optional<T>	37
3.8	Initialization Checker	38
3.8.1	Initialization qualifiers	39
3.8.2	How an object becomes initialized	40
3.8.3	@UnderInitialization examples	40
3.8.4	Partial initialization	42
3.8.5	Method calls from the constructor	42
3.8.6	Initialization of circular data structures	44
3.8.7	How to handle warnings	45
3.8.8	Suppressing warnings	46
3.8.9	More details about initialization checking	47
4	Map Key Checker	48
4.1	Map key annotations	48
4.2	Default annotations	48
4.2.1	Default for lower bounds	49
4.2.2	Diagnosing the need for explicit @KeyFor on lower bounds	49
4.3	Examples	50
4.4	Inference of @KeyFor annotations	50
5	Optional Checker for possibly-present data	52
5.1	How to run the Optional Checker	52
5.2	Optional annotations	52
5.3	What the Optional Checker guarantees	53
6	Interning Checker	54
6.1	Interning annotations	55
6.1.1	Interning qualifiers	55
6.1.2	Interning method and class annotations	55
6.2	Annotating your code with @Interned	55
6.3	Interned classes	55
6.3.1	The intern() methods	56
6.3.2	Default qualifiers and qualifiers for literals	56
6.3.3	InternedDistinct: values not equals() to any other value	57
6.4	What the Interning Checker checks	57
6.4.1	Imprecision (false positive warnings) of the Interning Checker	58
6.5	Examples	58
6.6	Other interning annotations	58
7	Lock Checker	59
7.1	What the Lock Checker guarantees	59
7.2	Lock annotations	59
7.2.1	Type qualifiers	59
7.2.2	Declaration annotations	61

7.3	Type-checking rules	61
7.3.1	Polymorphic qualifiers	61
7.3.2	Dereferences	62
7.3.3	Primitive types, boxed primitive types, and Strings	62
7.3.4	Overriding	62
7.3.5	Side effects	62
7.4	Examples	62
7.4.1	Examples of @GuardedBy	63
7.4.2	@GuardedBy({"a", "b"}) is not a subtype of @GuardedBy({"a"})	64
7.4.3	Examples of @Holding	64
7.4.4	Examples of @EnsuresLockHeld and @EnsuresLockHeldIf	65
7.4.5	Example of @LockingFree, @ReleasesNoLocks, and @MayReleaseLocks	65
7.4.6	Polymorphism and method formal parameters with unknown guards	66
7.5	More locking details	67
7.5.1	Two types of locking: monitor locks and explicit locks	67
7.5.2	Held locks and held expressions; aliasing	67
7.5.3	Run-time checks for locking	67
7.5.4	Discussion of default qualifier	68
7.5.5	Discussion of @Holding	68
7.6	Other lock annotations	69
7.6.1	Relationship to annotations in <i>Java Concurrency in Practice</i>	69
7.7	Possible extensions	69
8	Index Checker for sequence bounds (arrays and strings)	70
8.1	Index Checker structure and annotations	70
8.2	Lower bounds	71
8.3	Upper bounds	72
8.4	Sequence minimum lengths	73
8.5	Sequences of the same length	74
8.6	Binary search indices	75
8.7	Substring indices	76
8.7.1	The need for the @SubstringIndexFor annotation	77
8.8	Inequalities	78
8.9	Annotating fixed-size data structures	78
9	Fake Enum Checker for fake enumerations	80
9.1	Fake enum annotations	80
9.2	What the Fenum Checker checks	81
9.3	Running the Fenum Checker	81
9.4	Suppressing warnings	82
9.5	Example	82
9.6	The fake enumeration pattern	83
9.7	References	83
10	Tainting Checker	84
10.1	Tainting annotations	84
10.2	Tips on writing @Untainted annotations	84
10.3	@Tainted and @Untainted can be used for many purposes	85
10.4	A caution about polymorphism and side effects	85

11	Regex Checker for regular expression syntax	87
11.1	Regex annotations	87
11.2	Annotating your code with @Regex	87
11.2.1	Implicit qualifiers	87
11.2.2	Capturing groups	88
11.2.3	Concatenation of partial regular expressions	88
11.2.4	Testing whether a string is a regular expression	89
11.2.5	Suppressing warnings	89
12	Format String Checker	90
12.1	Formatting terminology	90
12.2	Format String Checker annotations	90
12.2.1	Conversion Categories	91
12.2.2	Subtyping rules for @Format	92
12.3	What the Format String Checker checks	93
12.3.1	Possible false alarms	94
12.3.2	Possible missed alarms	94
12.4	Implicit qualifiers	95
12.5	@FormatMethod	95
12.6	Testing whether a format string is valid	95
13	Internationalization Format String Checker (I18n Format String Checker)	97
13.1	Internationalization Format String Checker annotations	97
13.2	Conversion categories	98
13.3	Subtyping rules for @I18nFormat	98
13.4	What the Internationalization Format String Checker checks	99
13.5	Resource files	100
13.6	Running the Internationalization Format Checker	101
13.7	Testing whether a string has an i18n format type	101
13.8	Examples of using the Internationalization Format Checker	101
14	Property File Checker	103
14.1	General Property File Checker	103
14.2	Internationalization Checker (I18n Checker)	104
14.2.1	Internationalization annotations	104
14.2.2	Running the Internationalization Checker	104
14.3	Compiler Message Key Checker	104
15	Signature String Checker for string representations of types	106
15.1	Signature annotations	106
15.2	What the Signature Checker checks	108
16	GUI Effect Checker	109
16.1	GUI effect annotations	110
16.2	What the GUI Effect Checker checks	110
16.3	Running the GUI Effect Checker	110
16.4	Annotation defaults	110
16.5	Polymorphic effects	111
16.5.1	Defining an effect-polymorphic type	111
16.5.2	Using an effect-polymorphic type	111
16.5.3	Subclassing a specific instantiation of an effect-polymorphic type	112
16.5.4	Subtyping with polymorphic effects	112

16.6	References	113
17	Units Checker	114
17.1	Units annotations	114
17.2	Extending the Units Checker	115
17.3	What the Units Checker checks	116
17.4	Running the Units Checker	116
17.5	Suppressing warnings	116
17.6	References	117
18	Signedness Checker	118
18.1	Annotations	118
18.1.1	Default qualifiers	119
18.2	Prohibited operations	119
18.3	Rationale	119
18.4	Utility routines for manipulating unsigned values	120
18.5	Local type refinement	120
19	Aliasing Checker	121
19.1	Aliasing annotations	121
19.2	Leaking contexts	122
19.3	Restrictions on where @Unique may be written	123
19.4	Aliasing type refinement	123
20	Purity Checker	125
20.1	Purity annotations	125
20.2	Purity annotations are trusted	125
20.3	Overriding methods must respect specifications in superclasses	125
20.4	Suppressing warnings	126
21	Constant Value Checker	127
21.1	Annotations	127
21.1.1	Type Annotations	127
21.2	Other constant value annotations	128
21.2.1	Compile-time execution of expressions	129
21.2.2	@StaticallyExecutable methods and the classpath	129
21.3	Warnings	129
21.4	Unsoundly ignoring overflow	130
21.5	Strings can be null in concatenations	130
22	Returns Receiver Checker	132
22.1	Annotations	132
22.2	AutoValue and Lombok Support	132
23	Reflection resolution	134
23.1	Reflection resolution example	134
23.2	MethodVal and ClassVal Checkers	135
23.2.1	ClassVal Checker	135
23.2.2	MethodVal Checker	136
23.2.3	MethodVal and ClassVal inference	137

24	Subtyping Checker	138
24.1	Using the Subtyping Checker	138
24.1.1	Compiling your qualifiers and your project	138
24.1.2	Suppressing warnings from the Subtyping Checker	139
24.2	Subtyping Checker example	139
24.3	Type aliases and typedefs	141
25	Third-party checkers	143
25.1	Object Construction Checker	143
25.2	AWS crypto policy compliance checker	143
25.3	AWS KMS compliance checker	143
25.4	UI Thread Checker for ReactiveX	143
25.5	Glacier: Class immutability	144
25.6	SQL checker that supports multiple dialects	144
25.7	Read Checker for CERT FIO08-J	144
25.8	Nullness Rawness Checker	144
25.9	Immutability checkers: IGJ, OIGJ, and Javari	144
25.10	SPARTA information flow type-checker for Android	144
25.11	CheckLT taint checker	144
25.12	EnerJ checker	145
25.13	Generic Universe Types checker	145
25.14	Safety-Critical Java checker	145
25.15	Thread locality checker	145
25.16	Units and dimensions checker	145
25.17	Typestate checkers	145
25.17.1	Comparison to flow-sensitive type refinement	145
26	Generics and polymorphism	147
26.1	Generics (parametric polymorphism or type polymorphism)	147
26.1.1	Raw types	147
26.1.2	Restricting instantiation of a generic class	147
26.1.3	Type annotations on a use of a generic type variable	149
26.1.4	Annotations on wildcards	149
26.1.5	Examples of qualifiers on a type parameter	150
26.1.6	Covariant type parameters	151
26.1.7	Method type argument inference and type qualifiers	151
26.1.8	The Bottom type	152
26.2	Qualifier polymorphism	152
26.2.1	Examples of using polymorphic qualifiers	152
26.2.2	Relationship to subtyping and generics	153
26.2.3	Using multiple polymorphic qualifiers in a method signature	153
26.2.4	Using a single polymorphic qualifier in a method signature	153
27	Advanced type system features	155
27.1	Invariant array types	155
27.2	Context-sensitive type inference for array constructors	155
27.3	Upper bound of qualifiers on uses of a given type	156
27.4	The effective qualifier on a type (defaults and inference)	157
27.5	Default qualifier for unannotated types	157
27.5.1	Default for use of a type	158
27.5.2	Controlling defaults in source code	158
27.5.3	Defaulting rules and CLIMB-to-top	159

27.5.4	Inherited defaults	160
27.5.5	Inherited wildcard annotations	160
27.5.6	Default qualifiers for .class files (library defaults)	161
27.6	Annotations on constructors	162
27.6.1	Annotations on constructor declarations	162
27.6.2	Annotations on constructor invocations	162
27.7	Type refinement (flow-sensitive type qualifier inference)	162
27.7.1	Type refinement examples	163
27.7.2	Type refinement behavior	163
27.7.3	Which types are refined	163
27.7.4	Run-time tests and type refinement	164
27.7.5	Side effects, determinism, purity, and type refinement	165
27.7.6	Assertions	167
27.8	Writing Java expressions as annotation arguments	167
27.9	Field invariants	168
27.10	Unused fields	169
27.10.1	@Unused annotation	169
28	Suppressing warnings	171
28.1	@SuppressWarnings annotation	171
28.1.1	@SuppressWarnings syntax	172
28.1.2	Where @SuppressWarnings can be written	172
28.1.3	Good practices when suppressing warnings	173
28.2	@AssumeAssertion string in an assert message	174
28.2.1	Suppressing warnings and defensive programming	174
28.3	-AsuppressWarnings command-line option	175
28.4	-AskipUses and -AonlyUses command-line options	175
28.5	-AskipDefs and -AonlyDefs command-line options	176
28.6	-Alint command-line option	176
28.7	Don't run the processor	176
28.8	Checker-specific mechanisms	177
29	Handling legacy code	178
29.1	Checking partially-annotated programs: handling unannotated code	178
29.1.1	Declaration annotations	178
30	Type inference	180
30.1	Local type inference during type-checking	180
30.2	Type inference to annotate a program	180
30.2.1	Type inference tools	181
30.3	Whole-program inference	181
30.3.1	Whole-program inference ignores some code	182
30.3.2	Manually checking whole-program inference results	182
30.3.3	How whole-program inference works	183
31	Annotating libraries	184
31.1	Tips for annotating a library	185
31.1.1	Don't change the code	185
31.1.2	Library annotations should reflect the specification, not the implementation	185
31.1.3	Report bugs upstream	185
31.1.4	Fully annotate the library, or indicate which parts you did not	185
31.1.5	Verify your annotations	186

31.2	Creating an annotated library	186
31.3	Creating an annotated JDK	187
31.4	Compiling partially-annotated libraries	187
31.4.1	The <code>-AuseConservativeDefaultsForUncheckedCode=source,bytecode</code> command-line argument	187
31.5	Using stub classes	188
31.5.1	Using a stub file	188
31.5.2	Multiple specifications for a method	188
31.5.3	Stub file format	188
31.5.4	Creating a stub file	189
31.5.5	Troubleshooting stub libraries	190
31.6	Troubleshooting/debugging annotated libraries	191
32	How to create a new checker	192
32.1	How checkers build on the Checker Framework	193
32.2	The parts of a checker	193
32.3	Compiling and using a custom checker	194
32.4	Tips for creating a checker	194
32.5	Annotations: Type qualifiers and hierarchy	196
32.5.1	Defining the type qualifiers	196
32.5.2	Declaratively defining the qualifier hierarchy	197
32.5.3	Procedurally defining the qualifier hierarchy	198
32.5.4	Defining the default annotation	198
32.5.5	Relevant Java types	198
32.5.6	Do not re-use type qualifiers	198
32.5.7	Completeness of the type hierarchy	199
32.5.8	Annotations whose argument is a Java expression (dependent type annotations)	199
32.5.9	Repeatable annotations	200
32.6	The checker class: Compiler interface	200
32.6.1	Indicating supported annotations	201
32.6.2	Bundling multiple checkers	201
32.6.3	Providing command-line options	202
32.7	Visitor: Type rules	202
32.7.1	AST traversal	203
32.7.2	Avoid hardcoding	203
32.8	Type factory: Type introduction rules	204
32.8.1	Procedurally specifying type introduction rules	204
32.9	Dataflow: enhancing flow-sensitive type refinement	204
32.9.1	Determine expressions to refine the types of	204
32.9.2	Create required class	205
32.9.3	Override methods that handle Nodes of interest	205
32.9.4	Implement the refinement	206
32.9.5	Disabling flow-sensitive inference	207
32.10	Annotated JDK and other annotated libraries	207
32.11	Testing framework	208
32.12	Debugging options	208
32.12.1	Amount of detail in messages	208
32.12.2	Format of output	208
32.12.3	Stub and JDK libraries	209
32.12.4	Progress tracing	209
32.12.5	Saving the command-line arguments to a file	209
32.12.6	Visualizing the dataflow graph	209

32.12.7	Miscellaneous debugging options	210
32.12.8	Examples	210
32.12.9	Using an external debugger	210
32.13	Documenting the checker	211
32.14	javac implementation survival guide	211
32.14.1	Checker access to compiler information	212
32.14.2	How a checker fits in the compiler as an annotation processor	213
32.15	Integrating a checker with the Checker Framework	213
33	Integration with external tools	214
33.1	Android	214
33.2	Android Studio and the Android Gradle Plugin	214
33.2.1	JDK 8	215
33.2.2	JDK 11	216
33.3	Ant task	216
33.3.1	Explanation	217
33.4	Buck	217
33.5	Command line, via Checker Framework javac wrapper	218
33.6	Command line, via JDK javac	219
33.6.1	JDK 8	219
33.6.2	JDK 11	220
33.7	Eclipse	221
33.7.1	Using an Ant task	221
33.7.2	Troubleshooting Eclipse	221
33.8	Gradle	221
33.9	IntelliJ IDEA	221
33.10	javac diagnostics wrapper	222
33.11	Lombok	222
33.11.1	Annotations on generated code	222
33.11.2	Type-checking code with Lombok annotations	222
33.12	Maven	223
33.12.1	Maven, with a locally-modified version of the Checker Framework	225
33.13	NetBeans	225
33.13.1	Adding a checker via the Project Properties window	225
33.13.2	Adding a checker via an ant target	225
33.14	tIDE	226
33.15	Type inference tools	227
33.15.1	Local variable type inference within a method body	227
33.15.2	Type inference to annotate a program's source code	227
34	Frequently Asked Questions (FAQs)	228
34.1	Motivation for pluggable type-checking	229
34.1.1	I don't make type errors, so would pluggable type-checking help me?	229
34.1.2	Should I use pluggable types (type qualifiers), or should I use Java subtypes?	230
34.2	Getting started	231
34.2.1	How do I get started annotating an existing program?	231
34.2.2	Which checker should I start with?	231
34.2.3	How can I join the checker-framework-dev mailing list?	231
34.3	Usability of pluggable type-checking	231
34.3.1	Are type annotations easy to read and write?	231
34.3.2	Will my code become cluttered with type annotations?	232
34.3.3	Will using the Checker Framework slow down my program? Will it slow down the compiler?	232

34.3.4	How do I shorten the command line when invoking a checker?	232
34.3.5	Method pre-condition contracts, including formal parameter annotations, make no sense for public methods	232
34.4	How to handle warnings and errors	233
34.4.1	What should I do if a checker issues a warning about my code?	233
34.4.2	What does a certain Checker Framework warning message mean?	233
34.4.3	What do square brackets mean in a Checker Framework warning message?	233
34.4.4	Can a pluggable type-checker guarantee that my code is correct?	233
34.4.5	What guarantee does the Checker Framework give for concurrent code?	234
34.4.6	How do I make compilation succeed even if a checker issues errors?	234
34.4.7	Why does the checker always say there are 100 errors or warnings?	234
34.4.8	Why does the Checker Framework report an error regarding a type I have not written in my program?	234
34.4.9	Why does the Checker Framework accept code on one line but reject it on the next?	235
34.4.10	How can I do run-time monitoring of properties that were not statically checked?	235
34.5	False positive warnings	235
34.5.1	What is a “false positive” warning?	235
34.5.2	How can I improve the Checker Framework to eliminate a false positive warning?	235
34.5.3	Why doesn’t the Checker Framework infer types for fields and method return types?	236
34.5.4	Why doesn’t the Checker Framework track relationships between variables?	237
34.5.5	Why isn’t the Checker Framework path-sensitive?	238
34.6	Syntax of type annotations	239
34.6.1	What is a “receiver”?	239
34.6.2	What is the meaning of an annotation after a type, such as <code>@NonNull Object @Nullable?</code>	240
34.6.3	What is the meaning of array annotations such as <code>@NonNull Object @Nullable []?</code>	240
34.6.4	What is the meaning of varargs annotations such as <code>@English String @NotEmpty ...?</code>	240
34.6.5	What is the meaning of a type qualifier at a class declaration?	240
34.6.6	How are type qualifiers written on upper and lower bounds?	240
34.6.7	Why shouldn’t a qualifier apply to both types and declarations?	240
34.6.8	How do I annotate a fully-qualified type name?	241
34.6.9	What is the difference between type annotations and declaration annotations?	241
34.7	Semantics of type annotations	242
34.7.1	How can I handle typestate, or phases of my program with different data properties?	242

Chapter 1

Introduction

The Checker Framework enhances Java’s type system to make it more powerful and useful. This lets software developers detect and prevent errors in their Java programs.

A “checker” is a tool that warns you about certain errors or gives you a guarantee that those errors do not occur. The Checker Framework comes with checkers for specific types of errors:

1. Nullness Checker for null pointer errors (see Chapter 3, page 27)
2. Initialization Checker to ensure all fields are set in the constructor (see Chapter 3.8, page 38)
3. Map Key Checker to track which values are keys in a map (see Chapter 4, page 48)
4. Optional Checker for errors in using the `Optional` type (see Chapter 5, page 52)
5. Interning Checker for errors in equality testing and interning (see Chapter 6, page 54)
6. Lock Checker for concurrency and lock errors (see Chapter 7, page 59)
7. Index Checker for array accesses (see Chapter 8, page 70)
8. Fake Enum Checker to allow type-safe fake enum patterns and type aliases or typedefs (see Chapter 9, page 80)
9. Tainting Checker for trust and security errors (see Chapter 10, page 84)
10. Regex Checker to prevent use of syntactically invalid regular expressions (see Chapter 11, page 87)
11. Format String Checker to ensure that format strings have the right number and type of `%` directives (see Chapter 12, page 90)
12. Internationalization Format String Checker to ensure that `i18n` format strings have the right number and type of `{ }` directives (see Chapter 13, page 97)
13. Property File Checker to ensure that valid keys are used for property files and resource bundles (see Chapter 14, page 103)
14. Internationalization Checker to ensure that code is properly internationalized (see Chapter 14.2, page 104)
15. Signature String Checker to ensure that the string representation of a type is properly used, for example in `Class.forName` (see Chapter 15, page 106)
16. GUI Effect Checker to ensure that non-GUI threads do not access the UI, which would crash the application (see Chapter 16, page 109)
17. Units Checker to ensure operations are performed on correct units of measurement (see Chapter 17, page 114)
18. Signedness Checker to ensure unsigned and signed values are not mixed (see Chapter 18, page 118)
19. Aliasing Checker to identify whether expressions have aliases (see Chapter 19, page 121)
20. Purity Checker to identify whether methods have side effects (see Chapter 20, page 125)
21. Constant Value Checker to determine whether an expression’s value can be known at compile time (see Chapter 21, page 127)
22. Reflection Checker to determine whether an expression’s value (of type `Method` or `Class`) can be known at compile time (see Chapter 23, page 134)
23. Subtyping Checker for customized checking without writing any code (see Chapter 24, page 138)
24. Third-party checkers that are distributed separately from the Checker Framework (see Chapter 25, page 143)

These checkers are easy to use and are invoked as arguments to `javac`.

The Checker Framework also enables you to write new checkers of your own; see Chapters 24 and 32.

1.1 How to read this manual

If you wish to get started using some particular type system from the list above, then the most effective way to read this manual is:

- Read all of the introductory material (Chapters 1–2).
- Read just one of the descriptions of a particular type system and its checker (Chapters 3–25).
- Skim the advanced material that will enable you to make more effective use of a type system (Chapters 26–35), so that you will know what is available and can find it later. Skip Chapter 32 on creating a new checker.

1.2 How it works: Pluggable types

Java’s built-in type-checker finds and prevents many errors — but it doesn’t find and prevent *enough* errors. The Checker Framework lets you define new type systems and run them as a plug-in to the javac compiler. Your code stays completely backward-compatible: your code compiles with any Java compiler, it runs on any JVM, and your coworkers don’t have to use the enhanced type system if they don’t want to. You can check part of your program, or the whole thing. Type inference tools exist to help you annotate your code; see Section 30.2.

Most programmers will use type systems created by other people, such as those listed at the start of the introduction (Chapter 1, page 13). Some people, called “type system designers”, create new type systems (Chapter 32, page 192). The Checker Framework is useful both to programmers who wish to write error-free code, and to type system designers who wish to evaluate and deploy their type systems.

This document uses the terms “checker” and “type-checking compiler plugin” as synonyms.

1.3 Installation

This section describes how to install the Checker Framework.

- If you use a build system that automatically downloads dependencies, such as Gradle or Maven, **no installation is necessary**; just see Chapter 33, page 214.
- If you wish to try the Checker Framework without installing it, use the Checker Framework Live Demo webpage.
- This section describes how to install the Checker Framework from its distribution. The Checker Framework release contains everything that you need, both to run checkers and to write your own checkers.
- Alternately, you can build the latest development version from source (Section 35.3, page 254).

Requirement: You must have **JDK 8** or **JDK 11** installed. (The Checker Framework should work with any JDK 8–12, but we only test with JDK 8 and JDK 11.)

The installation process is simple! It has two required steps and one optional step.

1. Download the Checker Framework distribution:
`https://checkerframework.org/checker-framework-3.4.0.zip`
2. Unzip it to create a `checker-framework-3.4.0` directory.
3. Configure your IDE, build system, or command shell to include the Checker Framework on the classpath. Choose the appropriate section of Chapter 33.

That’s all there is to it! Now you are ready to start using the checkers.

We recommend that you work through the Checker Framework tutorial (<https://checkerframework.org/tutorial/>), which walks you through how to use the Checker Framework on the command line (Nullness, Regex, and Tainting Checkers). There is also a Nullness Checker tutorial (<https://github.com/glts/safer-spring-petclinic/wiki>) by David Bürgin; the setup instructions are out of date, but you can read through the steps.

Section 1.4 walks you through a simple example. More detailed instructions for using a checker appear in Chapter 2.

1.4 Example use: detecting a null pointer bug

This section gives a very simple example of running the Checker Framework. There is also a tutorial (<https://checkerframework.org/tutorial/>) that gives more extensive instructions for using the Checker Framework on the command line, and a Nullness Checker tutorial (<https://github.com/glts/safer-spring-petclinic/wiki>) by David Bürgin.

1. Let's consider this very simple Java class. The local variable `ref`'s type is annotated as `@NonNull`, indicating that `ref` must be a reference to a non-null object. Save the file as `GetStarted.java`.

```
import org.checkerframework.checker.nullness.qual.*;

public class GetStarted {
    void sample() {
        @NonNull Object ref = new Object();
    }
}
```

2. Run the Nullness Checker on the class. You can do that from the command line or from an IDE:

- (a) From the command line, run this command:

```
javac -processor org.checkerframework.checker.nullness.NullnessChecker GetStarted.java
```

where `javac` is set as in Section 33.5.

- (b) To compile within your IDE, you must have customized it to use the Checker Framework compiler and to pass the extra arguments (see Chapter 33).

The compilation should complete without any errors.

3. Let's introduce an error now. Modify `ref`'s assignment to:

```
@NonNull Object ref = null;
```

4. Run the Nullness Checker again, just as before. This run should emit the following error:

```
GetStarted.java:5: incompatible types.
found   : @Nullable <nulltype>
required: @NonNull Object
        @NonNull Object ref = null;
                                   ^
1 error
```

The type qualifiers (e.g., `@NonNull`) are permitted anywhere that you can write a type, including generics and casts; see Section 2.1. Here are some examples:

```
@Interned String intern() { ... }           // return value
int compareTo(@NonNull String other) { ... } // parameter
@NonNull List<@Interned String> messages;    // non-null list of interned Strings
```

Chapter 2

Using a checker

A pluggable type-checker enables you to detect certain bugs in your code, or to prove that they are not present. The verification happens at compile time.

Finding bugs, or verifying their absence, with a checker is a two-step process, whose steps are described in Sections 2.1 and 2.2.

1. The programmer writes annotations, such as `@NonNull` and `@Interned`, that specify additional information about Java types. (Or, the programmer uses an inference tool to automatically insert annotations in his code: see Section 3.3.8.) It is possible to annotate only part of your code: see Section 29.1.
2. The checker reports whether the program contains any erroneous code — that is, code that is inconsistent with the annotations.

This chapter is structured as follows:

- Section 2.1: How to write annotations
- Section 2.2: How to run a checker
- Section 2.3: What the checker guarantees
- Section 2.4: Tips about writing annotations

Additional topics that apply to all checkers are covered later in the manual:

- Chapter 27: Advanced type system features
- Chapter 28: Suppressing warnings
- Chapter 29: Handling legacy code
- Chapter 31: Annotating libraries
- Chapter 32: How to create a new checker
- Chapter 33: Integration with external tools

There is a tutorial (<https://checkerframework.org/tutorial/>) that walks you through using the Checker Framework on the command line. There is also a Nullness Checker tutorial (<https://github.com/glts/safer-spring-petclinic/wiki>) by David Burgin (last updated in April 2016).

2.1 Where to write type annotations

You may write a type annotation immediately before any use of a type, including in generics and casts. Because array levels are types and receivers have types, you can also write type annotations on them. Here are a few examples of type annotations:

```
@Interned String intern() { ... }           // return value  
int compareTo(@NonNull String other) { ... } // parameter
```

```
String toString(@Tainted MyClass this) { ... } // receiver ("this" parameter)
@NonNull List<@Interned String> messages;      // generics: non-null list of interned Strings
@Interned String @NonNull [] messages;        // arrays: non-null array of interned Strings
myDate = (@Initialized Date) beingConstructed; // cast
```

You only need to write type annotations on method signatures, fields, and some type arguments. Most annotations within method bodies are inferred for you; for more details, see Section 27.7.

The Java Language Specification also defines declaration annotations, such as `@Deprecated` and `@Override`, which apply to a class, method, or field but do not apply to the method's return type or the field's type. They should be written on their own line in the source code.

2.2 Running a checker

To run a checker, run the compiler `javac` as usual, but either pass the `-processor plugin_class` command-line option, or use auto-discovery as described in Section 2.2.3. A concrete example of using `-processor` to run the Nullness Checker is:

```
javac -processor nullness MyFile.java
```

where `javac` is as specified in Section 33.5.

You can also run a checker from within your favorite IDE or build system. See Chapter 33 for details about build tools such as Ant (Section 33.3), Buck (Section 33.4), Gradle (Section 33.8), and Maven (Section 33.12); IDEs such as IntelliJ IDEA (Section 33.9), Eclipse (Section 33.7), NetBeans (Section 33.13), and tIDE (Section 33.14); and about customizing other IDEs and build tools.

The checker is run on only the Java files that `javac` compiles. This includes all Java files specified on the command line and those created by another annotation processor. It may also include other of your Java files, if they are more recent than the corresponding `.class` file. Even when the checker does not analyze a class (say, the class was already compiled, or source code is not available), it does check the *uses* of those classes in the source code being compiled. Type-checking works modularly and intraprocedurally: when verifying a method, it examines only the signature (including annotations) of other methods, not their implementations.

After you compile your code while running a checker, the resulting `.class` and `.jar` files can be used for pluggable type-checking of client code.

If you compile code without the `-processor` command-line option, no checking of the type annotations is performed. Furthermore, only explicitly-written annotations are written to the `.class` file; defaulted annotations are not, and this will interfere with type-checking of clients that use your code. Therefore, you create `.class` files that will be distributed or compiled against, you should run the type-checkers for all the annotations that you have written.

2.2.1 Using annotated libraries

When your code uses a library that is not currently being compiled, the Checker Framework looks up the library's annotations in its class files.

Some projects are already distributed with type annotations by their maintainers, so you do not need to do anything special. An example is all the libraries in <https://github.com/plume-lib/>. Over time, this should become more common.

For some other libraries, the Checker Framework developers have provided an annotated version of the library. The annotated libraries appear in the `org.checkerframework.annotatedlib` group in the Central Repository. The annotated library has *identical* behavior to the upstream, unannotated version; the source code is identical other than added annotations. (Some of the annotated libraries are `bcel`, `commons-csv`, `commons-io`, `guava`, and `java-getopt`. If the library you are interested in does not appear in the Central Repository, you can contribute by annotating it, which will help you and all other Checker Framework users; see Chapter 31, page 184.)

To use an annotated library:

- If your project stores `.jar` files locally, then download the `.jar` file from the Central Repository.

- If your project manages dependencies using a tool such as Gradle or Maven, then update your buildfile to use the `org.checkerframework.annotatedlib` group. For example, in `build.gradle`, change

```
api group: 'org.apache.bcel', name: 'bcel', version: '6.3.1'
api group: 'commons-io', name: 'commons-io', version: '2.6'
```

to

```
api group: 'org.checkerframework.annotatedlib', name: 'bcel', version: '6.3.1'
api group: 'org.checkerframework.annotatedlib', name: 'commons-io', version: '2.6.0.1'
```

Usually use the same version number. (Sometimes you will use a slightly larger number, if the Checker Framework developers have improved the type annotations since the last release by the upstream maintainers.) If a newer version of the upstream library is available but that version is not available in `org.checkerframework.annotatedlib`, then open an issue requesting that the `org.checkerframework.annotatedlib` version be updated.

There is one special case.

- For the Java 8 version of the Javadoc classes in the JDK's `com.sun.javadoc` package, use the stub file `checker/resources/javadoc.astub` by using `-Astubs=checker.jar/javadoc.astub`. The “`checker.jar`” should be literal — don't provide a path. (This special syntax only works for “`checker.jar`”.)

2.2.2 Summary of command-line options

You can pass command-line arguments to a checker via `javac`'s standard `-A` option (“A” stands for “annotation”). All of the distributed checkers support the following command-line options. Each checker may support additional command-line options; see the checker's documentation.

To pass an option to only a particular checker, prefix the option with the canonical or simple name of a checker, separated by an underscore “_”. Such an option will apply only to a checker with that name or any subclass of that checker. For example, you can use

```
-ANullnessChecker_lint=redundantNullComparison
-Aorg.checkerframework.checker.guieffect.GuiEffectChecker_lint=debugSpew
```

to pass different lint options to the Nullness and GUI Effect Checkers.

Unsound checking: ignore some errors

- `-AsuppressWarnings` Suppress all errors and warnings matching the given key; see Section 28.3.
- `-AskipUses`, `-AonlyUses` Suppress all errors and warnings at all uses of a given class — or at all uses except those of a given class. See Section 28.4.
- `-AskipDefs`, `-AonlyDefs` Suppress all errors and warnings within the definition of a given class — or everywhere except within the definition of a given class. See Section 28.5.
- `-AassumeSideEffectFree`, `-AassumeDeterministic`, `-AassumePure` Unsoundly assume that every method is side-effect-free, deterministic, or both; see Section 27.7.5.
- `-AassumeAssertionsAreEnabled`, `-AassumeAssertionsAreDisabled` Whether to assume that assertions are enabled or disabled; see Section 27.7.6.
- `-AignoreRangeOverflow` Ignore the possibility of overflow for range annotations such as `@IntRange`; see Section 21.4.
- `-Awarns` Treat checker errors as warnings. If you use this, you may wish to also supply `-Xmaxwarns 10000`, because by default `javac` prints at most 100 warnings. If you use this, don't supply `-Werror`, which is a `javac` argument to halt compilation if a warning is issued.
- `-AignoreInvalidAnnotationLocations` Ignore annotations in bytecode that have invalid annotation locations.

More sound (strict) checking: enable errors that are disabled by default

- `-AcheckPurityAnnotations` Check the bodies of methods marked `@SideEffectFree`, `@Deterministic`, and `@Pure` to ensure the method satisfies the annotation. By default, the Checker Framework unsoundly trusts the method annotation. See Section 27.7.5.

- `-AinvariantArrays` Make array subtyping invariant; that is, two arrays are subtypes of one another only if they have exactly the same element type. By default, the Checker Framework unsoundly permits covariant array subtyping, just as Java does. See Section 27.1.
- `-AcheckCastElementType` In a cast, require that parameterized type arguments and array elements are the same. By default, the Checker Framework unsoundly permits them to differ, just as Java does. See Section 26.1.6 and Section 27.1.
- `-AuseConservativeDefaultsForUncheckedCode` Enables/disables conservative defaults in unchecked code. Takes arguments “source,bytecode”. “-source,-bytecode” is the (unsound) default setting.
 - “bytecode” specifies whether the checker should apply conservative defaults to bytecode (that is, to already-compiled libraries); see Section 27.5.6.
 - Outside the scope of any relevant `@AnnotatedFor` annotation, “source” specifies whether conservative default annotations are applied to source code and suppress all type-checking warnings; see Section 31.4.
- `-AconcurrentSemantics` Whether to assume concurrent semantics (field values may change at any time) or sequential semantics; see Section 34.4.5.
- `-AconservativeUninferredTypeArguments` Whether an error should be issued if type arguments could not be inferred and whether method type arguments that could not be inferred should use conservative defaults. By default, such type arguments are (largely) ignored in later checks. Passing this option uses a conservative value instead. See Issue 979.
- `-AignoreRawTypeArguments=false` Do not ignore subtype tests for type arguments that were inferred for a raw type. Must also use `-AconservativeUninferredTypeArguments`. See Section 26.1.1.

Type-checking modes: enable/disable functionality

- `-Aint` Enable or disable optional checks; see Section 28.6.
- `-AsuggestPureMethods` Suggest methods that could be marked `@SideEffectFree`, `@Deterministic`, or `@Pure`; see Section 27.7.5.
- `-AresolveReflection` Determine the target of reflective calls, and perform more precise type-checking based on that information; see Chapter 23. `-AresolveReflection=debug` causes debugging information to be output.
- `-Ainfer` Output suggested annotations for method signatures and fields. These annotations may reduce the number of type-checking errors when running type-checking in the future; see Section 30.3.
- `-AshowSuppressWarningKeys` With each warning, show all possible keys to suppress that warning.
- `-AwarnUnneededSuppressions` Issue a warning if a `@SuppressWarnings` did not suppress a warning issued by the checker. This may issue false positive warnings about `@SuppressWarnings` keys without a `checkername:` prefix (Section 28.1.1). You can use the `-ArequirePrefixInWarningSuppressions` command-line argument to ensure your `@SuppressWarnings` always use a `checkername:` prefix.
- `-ArequirePrefixInWarningSuppressions` Require that the key in a warning suppression annotation begin with a checker warning suppression key. Otherwise, the suppress warning annotation does not suppress any warnings. For example, if this command-line option is supplied, then `@SuppressWarnings("assignment.type.incompatible")` has no effect, but `@SuppressWarnings("nullness:assignment.type.incompatible")` does.

Partially-annotated libraries

- `-Astubs` List of stub files or directories; see Section 31.5.1.
- `-AstubWarnIfNotFound` Warn if a stub file entry could not be found; see Section 31.5.1.
- `-AstubWarnIfNotFoundIgnoresClasses` Don’t warn about missing classes (only methods and fields) even when `-AstubWarnIfNotFound` is true.
- `-AstubWarnIfRedundantWithBytecode` Warn if a stub file entry is redundant with bytecode information; see Section 31.5.1.
- `-AuseConservativeDefaultsForUncheckedCode=source` Outside the scope of any relevant `@AnnotatedFor` annotation, use conservative default annotations and suppress all type-checking warnings; see Section 31.4.

Debugging

- `-AprintAllQualifiers`, `-AprintVerboseGenerics`, `-Anomsgtext` Amount of detail in messages; see Section 32.12.1.
- `-Adetailedmsgtext` Format of diagnostic messages; see Section 32.12.2.
- `-Aignorejdkastub`, `-ApermitMissingJdk`, `-AparseAllJdk`, `-AstubDebug` Stub and JDK libraries; see Section 32.12.3.
- `-Afilenames`, `-Ashowchecks`, `-AshowInferenceSteps` Progress tracing; see Section 32.12.4.
- `-AoutputArgsToFile` Output the compiler command-line arguments to a file. Useful when the command line is generated and executed by a tool, such as a build system. This produces a standalone command line that can be executed independently of the tool that generated it (such as a build system). That command line makes it easier to reproduce, report, and debug issues. For example, the command line can be modified to enable attaching a debugger. See Section 32.12.5.
- `-Aflowdotdir`, `-Averbosecfg`, `-Acfgviz` Draw a visualization of the CFG (control flow graph); see Section 32.12.6.
- `-AresourceStats`, `-AatfDoNotCache`, `-AatfCacheSize` Miscellaneous debugging options; see Section 32.12.7.
- `-AprintGitProperties` Print information about the git repository from which the Checker Framework was compiled.

Some checkers support additional options, which are described in that checker’s manual section. For example, `-Aequals` tells the Subtyping Checker (see Chapter 24) and the Fenum Checker (see Chapter 9) which annotations to check.

Here are some standard `javac` command-line options that you may find useful. Many of them contain the word “processor”, because in `javac` jargon, a checker is an “annotation processor”.

- `-processor` Names the checker to be run; see Sections 2.2 and 2.2.4. May be a comma-separated list of multiple checkers. Note that `javac` stops processing an indeterminate time after detecting an error. When providing multiple checkers, if one checker detects any error, subsequent checkers may not run.
- `-processorpath` Indicates where to search for the checker; should also contain any qualifiers used by the Subtyping Checker; see Section 24.2
- `-proc:{none,only}` Controls whether checking happens; `-proc:none` means to skip checking; `-proc:only` means to do only checking, without any subsequent compilation; see Section 2.2.3
- `-implicit:class` Suppresses warnings about implicitly compiled files (not named on the command line); see Section 33.3
- `-J` Supply an argument to the JVM that is running `javac`; for example, `-J-Xmx2500m` to increase its maximum heap size
- `-doe` To “dump on error”, that is, output a stack trace whenever a compiler warning/error is produced. Useful when debugging the compiler or a checker.

The Checker Framework does not support `-source 1.7` or earlier. You must supply `-source 1.8` or later, or no `-source` command-line argument, when running `javac`.

2.2.3 Checker auto-discovery

“Auto-discovery” makes the `javac` compiler always run a checker plugin, even if you do not explicitly pass the `-processor` command-line option. This can make your command line shorter, and ensures that your code is checked even if you forget the command-line option.

To enable auto-discovery, place a configuration file named `META-INF/services/javac.annotation.processing.Processor` in your classpath. The file contains the names of the checkers to be used, listed one per line. For instance, to run the Nullness Checker and the Interning Checker automatically, the configuration file should contain:

```
org.checkerframework.checker.nullness.NullnessChecker
org.checkerframework.checker.interning.InterningChecker
```

You can disable this auto-discovery mechanism by passing the `-proc:none` command-line option to `javac`, which disables all annotation processing including all pluggable type-checking.

2.2.4 Shorthand for built-in checkers

Ordinarily, `javac`'s `-processor` flag requires fully-qualified class names. When running a built-in checker, you may omit the package name and the Checker suffix. The following three commands are equivalent:

```
javac -processor org.checkerframework.checker.nullness.NullnessChecker MyFile.java
javac -processor NullnessChecker MyFile.java
javac -processor nullness MyFile.java
```

This feature also works when multiple checkers are specified. Their names are separated by commas, with no surrounding space. For example:

```
javac -processor NullnessChecker,RegexChecker MyFile.java
javac -processor nullness,regex MyFile.java
```

This feature does not apply to `javac @argfiles`.

2.3 What the checker guarantees

A checker guarantees that a particular property holds throughout the code.

For example, the Nullness Checker (Chapter 3) guarantees lack of null pointer exceptions; more precisely, it guarantees that only expressions whose type is a `@NonNull` type are dereferenced, and that such expressions never evaluate to null. The Interning Checker (Chapter 6) guarantees that every expression whose type is an `@Interned` type evaluates to an interned value, and thereby it prevents incorrect equality tests.

The guarantee holds only if you run the checker on every part of your program and the checker issues no warnings anywhere in the code. You can also verify just part of your program.

There are some limitations to the guarantee.

- A compiler plugin can check only those parts of your program that you run it on. If you compile some parts of your program without running the checker, then there is no guarantee that the entire program satisfies the property being checked. Some examples of un-checked code are:
 - Code compiled without the `-processor` switch, including any external library supplied as a `.class` file.
 - Code compiled with the `-AskipUses`, `-AonlyUses`, `-AskipDefs` or `-AonlyDefs` properties (see Chapter 28).
 - Native methods (because the implementation is not Java code, it cannot be checked).
 - Dynamically generated code, such as generated by Spring or MyBatis. Its bytecode is directly generated and run, not compiled by `javac` and not visible to the Checker Framework.

In each of these cases, any *use* of the code is checked — for example, a call to a native method must be compatible with any annotations on the native method's signature. However, the annotations on the un-checked code are trusted; there is no verification that the implementation of the native method satisfies the annotations.

- You can suppress warnings, such as via the `@SuppressWarnings` annotation (Chapter 28, page 171). If you do so incorrectly, the checker's guarantee no longer holds.
- The Checker Framework is, by default, unsound in a few places where a conservative analysis would issue too many false positive warnings. These are listed in Section 2.2.2. You can supply a command-line argument to make the Checker Framework sound for each of these cases.
- Specific checkers may have other limitations; see their documentation for details.

In order to avoid a flood of unhelpful warnings, many of the checkers avoid issuing the same warning multiple times. For example, in this code:

```
@Nullable Object x = ...;
x.toString();           // warning
x.toString();           // no warning
```

In this case, the second call to `toString` cannot possibly throw a null pointer warning — `x` is non-null if control flows to the second statement. In other cases, a checker avoids issuing later warnings with the same cause even when later code in a method might also fail. This does not affect the soundness guarantee, but a user may need to examine more warnings after fixing the first ones identified. (Often, a single fix corrects all the warnings.)

If you find that a checker fails to issue a warning that it should, then please report a bug (see Section 35.2).

2.4 Tips about writing annotations

Section 31.1 gives additional tips that are specific to annotating a third-party library.

2.4.1 Write annotations before you run a checker

Before you run a checker, annotate the code, based on its documentation. Then, run the checker to uncover bugs in the code or the documentation.

Don't do the opposite, which is to run the checker and then add annotations according to the warnings issued. This approach is less systematic, so you may overlook some annotations. It often leads to confusion and poor results. It leads users to make changes not for any principled reason, but to “make the type-checker happy”, even when the changes are in conflict with the documentation or the code. Also see “Annotations are a specification”, below.

2.4.2 How to get started annotating legacy code

Annotating an entire existing program may seem like a daunting task. But, if you approach it systematically and do a little bit at a time, you will find that it is manageable.

Start small

Start small. Focus on one specific property that matters to you; in other words, run just one checker rather than multiple ones. You may choose a different checker for different programs. Focus on the most mission-critical or error-prone part of your code; don't try to annotate your whole program at first.

It is easiest to add annotations if you know the code or the code contains documentation; you will find that you spend most of your time understanding the code, and very little time actually writing annotations or running the checker.

When annotating, be systematic; we recommend annotating an entire class at a time (not just some of the methods) so that you don't lose track of your work or redo work. For example, working class-by-class avoids confusion about whether an unannotated type means you determined that the default is desirable, or it means you didn't yet examine that type. You may find it helpful to start annotating the leaves of the call tree — that is, start with methods/classes/packages that have few dependencies on other code or, equivalently, start with code that a lot of your other code depends on. For example, within a package annotate supertypes before you annotated classes that extend or implement them. The reason for this rule is that it is easiest to annotate a class if the code it depends on has already been annotated.

Don't overuse pluggable type-checking. If the regular Java type system can verify a property using Java subclasses, then that is a better choice than pluggable type-checking (see Section 34.1.2).

Annotations are a specification

When you write annotations, you are writing a specification, and you should think about them that way. Start out by understanding the program so that you can write an accurate specification. Sections 2.4.3 and 2.4.4 give more tips about writing specifications.

For each class, read its Javadoc. For instance, if you are adding annotations for the Nullness Checker (Section 3), then you can search the documentation for “null” and then add `Nullable` anywhere appropriate. For now, just annotate signatures and fields; there is no need to annotate method bodies. The only reason to even *read* the method bodies yet is to determine signature annotations for undocumented methods — for example, if the method returns null, you know its

return type should be annotated `@Nullable`, and a parameter that is compared against `null` may need to be annotated `@Nullable`.

The specification should state any facts that are relevant to callees. When checking a method, uses only the specification, not the implementation, of other methods. (Equivalently, type-checking is “modular” or “intraprocedural”.)

After you have annotated all the signatures, run the checker. Then, fix bugs in code and add/modify annotations as necessary. Don’t get discouraged if you see many type-checker warnings at first. Often, adding just a few missing annotations will eliminate many warnings, and you’ll be surprised how fast the process goes overall.

You may wonder about the effect of adding a given annotation (that is, of changing the specification for a given method or class): how many other specification changes (added annotations) will it require, and will it conflict with other code? It’s best to reason about the desired design, but you can also do an experiment. Suppose you are considering adding an annotation to a method parameter. One approach is to manually examine all callees. A more automated approach is to save the checker output before adding the annotation, and to compare it to the checker output after adding the annotation. This helps you to focus on the specific consequences of your change.

Chapter 31 tells you how to annotate libraries that your code uses. Section 2.4.5 and Chapter 28 tell you what to do when you are unable to eliminate checker warnings by adding annotations.

Write good code

Avoid complex code, which is more error-prone. If you write your code to be simple and clean enough for the type-checker to verify, then it will also be easier for programmers to understand.

Your code should compile cleanly under the regular Java compiler. If you are not willing to write code that type-checks in Java, then there is little point in using an even more powerful, restrictive type system. As a specific example, your code should not use raw types like `List`; use parameterized types like `List<String>` instead (Section 26.1.1).

Do not write unnecessary annotations.

- Do not annotate local variables unless necessary. The checker infers annotations for local variables (see Section 27.7). Usually, you only need to annotate fields and method signatures. You should add annotations inside method bodies only if the checker is unable to infer the correct annotation (usually on type arguments or array element types, rather than on top-level types).
- Do not write annotations that are redundant with defaults. For example, when checking nullness (Chapter 3, page 27), the default annotation is `@NonNull`, in most locations other than some type bounds (Section 27.5.3). When you are starting out, it might seem helpful to write redundant annotations as a reminder, but that’s like when beginning programmers write a comment about every simple piece of code:

```
// The below code increments variable i by adding 1 to it.  
i++;
```

As you become comfortable with pluggable type-checking, you will find redundant annotations to be distracting clutter, so avoid putting them in your code in the first place.

- Avoid writing `@SuppressWarnings` annotations unless there is no alternative. It is tempting to think that your code is right and the checker’s warnings are false positives. Sometimes they are, but slow down and convince yourself of that before you dismiss them. Section 2.4.5 discusses what to do when a checker issues a warning about your code.

2.4.3 Annotations indicate non-exceptional behavior

You should use annotations to specify *normal* behavior. The annotations indicate all the values that you *want* to flow to a reference — not every value that might possibly flow there if your program has a bug.

As an example, the goal of the Nullness Checker is to guarantee that your program does not crash due to a null value. In a method like this:

```
/** @throws IllegalArgumentException if arg is null */  
void m(Object arg) {  
    if (arg == null) {
```

```

        throw new IllegalArgumentException();
    }
    ...
}

```

the program crashes if `null` is passed. Therefore, the type of `arg` should be `@NonNull Object` (which you can write as just `Object` due to defaulting). The Nullness Checker (Chapter 3, page 27) will warn whenever a client passes a value that might cause `m` to crash. If you wrote the type of the formal parameter as `@Nullable Object`, the Nullness Checker would permit clients to make calls that lead to a crash.

Many methods are guaranteed to throw an exception if they are passed `null` as an argument. Examples include

```

java.lang.Double.valueOf(String)
java.lang.String.contains(CharSequence)
org.junit.Assert.assertNotNull(Object)
com.google.common.base.Preconditions.checkNotNull(Object)

```

`@Nullable` (see Section 3.2) might seem like a reasonable annotation for the parameter, for two reasons. First, `null` is a legal argument with a well-defined semantics: throw an exception. Second, `@Nullable` describes a possible program execution: it might be possible for `null` to flow there, if your program has a bug.

However, it is never useful for a programmer to pass `null`. It is the programmer's intention that `null` never flows there. If `null` does flow there, the program will not continue normally (whether or not it throws a `NullPointerException`).

Therefore, you should specify such parameters as `@NonNull`, indicating the intended use of the method. When you specify the parameter as the `@NonNull` annotation, the checker is able to issue compile-time warnings about possible run-time exceptions, which is its purpose. Specifying the parameter as `@Nullable` would suppress such warnings, which is undesirable. (Since `@NonNull` is the default, you don't have to write anything in the source code to specify the parameter as non-null. You are allowed to write a redundant `@NonNull` annotation, but it is discouraged.)

If a method can possibly throw an exception because its parameter is `null`, then that parameter's type should be `@NonNull`, which guarantees that the type-checker will issue a warning for every client use that has the potential to cause an exception. Don't write `@Nullable` on the parameter just because there exist some executions that don't necessarily throw an exception.

Another example is the Optional Checker (Chapter 5, page 52) and the `orElseThrow` method. The goal of the Optional Checker is to ensure that the program does not crash due to use of a non-present Optional value. Therefore, the receiver of `orElseThrow` is annotated as `@Present`, and the optional Checker issues a warning if the client calls `orElseThrow` on a `@MaybePresent` value.

2.4.4 Subclasses must respect superclass annotations

An annotation indicates a guarantee that a client can depend upon. A subclass is not permitted to *weaken* the contract; for example, if a method accepts `null` as an argument, then every overriding definition must also accept `null`. A subclass is permitted to *strengthen* the contract; for example, if a method does *not* accept `null` as an argument, then an overriding definition is permitted to accept `null`.

As a bad example, consider an erroneous `@Nullable` annotation in `com/google/common/collect/Multiset.java`:

```

101 public interface Multiset<E> extends Collection<E> {
...
122 /**
123  * Adds a number of occurrences of an element to this multiset.
...
129  * @param element the element to add occurrences of; may be {@code null} only
130  *     if explicitly allowed by the implementation
...
137  * @throws NullPointerException if {@code element} is null and this

```

```

138     *      implementation does not permit null elements. Note that if {@code
139     *      occurrences} is zero, the implementation may opt to return normally.
140     */
141     int add(@Nullable E element, int occurrences);

```

There exist implementations of `Multiset` that permit null elements, and implementations of `Multiset` that do not permit null elements. A client with a variable `Multiset ms` does not know which variety of `Multiset` `ms` refers to. However, the `@Nullable` annotation promises that `ms.add(null, 1)` is permissible. (Recall from Section 2.4.3 that annotations should indicate normal behavior.)

If parameter `element` on line 141 were to be annotated, the correct annotation would be `@NonNull`. Suppose a client has a reference to same `Multiset ms`. The only way the client can be sure not to throw an exception is to pass only non-null elements to `ms.add()`. A particular class that implements `Multiset` could declare `add` to take a `@Nullable` parameter. That still satisfies the original contract. It strengthens the contract by promising even more: a client with such a reference can pass any non-null value to `add()`, and may also pass `null`.

However, the best annotation for line 141 is no annotation at all. The reason is that each implementation of the `Multiset` interface should specify its own nullness properties when it specifies the type parameter for `Multiset`. For example, two clients could be written as

```

class MyNullPermittingMultiset implements Multiset<@Nullable Object> { ... }
class MyNullProhibitingMultiset implements Multiset<@NonNull Object> { ... }

```

or, more generally, as

```

class MyNullPermittingMultiset<E extends @Nullable Object> implements Multiset<E> { ... }
class MyNullProhibitingMultiset<E extends @NonNull Object> implements Multiset<E> { ... }

```

Then, the specification is more informative, and the Checker Framework is able to do more precise checking, than if line 141 has an annotation.

It is a pleasant feature of the Checker Framework that in many cases, no annotations at all are needed on type parameters such as `E` in `Multiset`.

2.4.5 What to do if a checker issues a warning about your code

When you run a type-checker on your code, it is likely to issue warnings or errors. Don't panic! There are three general causes for the warnings:

- There is a bug in your code, such as a possible null dereference. Fix your code to prevent that crash.
- The annotations are too strong (they are incorrect) or too weak (they are imprecise). Improve the annotations, usually by writing more annotations in order to better express the specification. Only write annotations that accurately describe the intended behavior of the software — don't write inaccurate annotations just for the purpose of eliminating type-checker warnings.

Usually you need to improve the annotations in your source code. Sometimes you need to improve annotations in a library that your program uses (see Chapter 31, page 184).

- There is a weakness in the type-checker. Your code is safe — it never suffers the error at run time — but the checker cannot prove this fact. If possible, rewrite your code to be simpler for the checker to analyze; this is likely to make it easier for people to understand, too. If that is not possible, suppress the warning (see Chapter 28); be sure to include a code comment explaining how you know the code is correct even though the type-checker cannot deduce that fact.

(Do not add an `if` test that can never fail, just to suppress a warning. Adding a gratuitous `if` clutters the code and confuses readers, who will assume that every `if` condition can evaluate to true or false. It can be acceptable to add an `if` test that throws a descriptive error message.)

For each warning issued by the checker, you need to determine which of the above categories it falls into. Here is an effective methodology to do so. It relies mostly on manual code examination, but you may also find it useful to write test cases for your code or do other kinds of analysis, to verify your reasoning.

1. Write an explanation of why your code is correct and it never suffers the error at run time. In other words, this is an English proof that the type-checker's warning is incorrect.
Don't skip any steps in your proof. (For example, don't write an unsubstantiated claim such as "x is non-null here"; instead, give a justification.) Don't let your reasoning rely on facts that you do not write down explicitly. For example, remember that calling a method might change the values of object fields; your proof might need to state that certain methods have no side effects.
If you cannot write a proof, then there is a bug in your code (you should fix the bug) or your code is too complex for you to understand (you should improve its documentation and/or design).
2. Translate the proof into annotations. Here are some examples.
 - If your proof includes "variable x is never null at run time", then annotate x's type with `@NonNull`.
 - If your proof includes "method foo always returns a legal regular expression", then annotate foo's return type with `@Regex`.
 - If your proof includes "if method join's first argument is non-null, then join returns a non-null result", then annotate join's first parameter and return type with `@PolyNull`.
 - If your proof includes "method processOptions has already been called and it set field tz1", then annotate processOptions's declaration with `@EnsuresNonNull("tz1")`.
 - If your proof includes "method isEmpty returned false, so its argument must have been non-null", then annotate isEmpty's declaration with `@EnsuresNonNullIf(expression="#1", result=false)`.

All of these are examples of correcting weaknesses in the annotations you wrote. The Checker Framework provides many other powerful annotations; you may be surprised how many proofs you can express in annotations. If you need to annotate a method that is defined in a library that your code uses, see Chapter 31, page 184.

Don't omit any parts of your proof. When the Checker Framework analyzes a method, it examines only the specifications (not the implementations) of other methods.

If there are complex facts in your proof that cannot be expressed as annotations, then that is a weakness in the type-checker. For example, the Nullness Checker cannot express "in list `lst`, elements stored at even indices are always non-null, but elements stored at odd elements might be null." In this case, you have two choices. First, you can suppress the warning (Chapter 28, page 171); be sure to write a comment explaining your reasoning for suppressing the warning. You may wish to submit a feature request (Section 35.2) asking for annotations that handle your use case. Second, you can rewrite the code to make the proof simpler; in the above example, it might be better to use a list of pairs rather than a heterogeneous list.

3. At this point, all the steps in your proof have been formalized as annotations. Re-run the checker and repeat the process for any new or remaining warnings.

If every step of your proof can be expressed in annotations, but the checker cannot make one of the deductions (it cannot follow one of the steps), then that is a weakness in the type-checker. First, double-check your reasoning. Then, suppress the warning, along with a comment explaining your reasoning (Chapter 28, page 171). The comment is an excerpt from your English proof, and the proof guides you to the best place to suppress the warning. Finally, please submit a bug report so that the checker can be improved in the future (Section 35.2).

If you have trouble understanding a Checker Framework warning message, you can search for its text in this manual. Also see Section 35.1.4 and Chapter 35, Troubleshooting. In particular, Section 35.1.4 explains this same methodology in different words.

Chapter 3

Nullness Checker

If the Nullness Checker issues no warnings for a given program, then running that program will never throw a null pointer exception. This guarantee enables a programmer to prevent errors from occurring when a program is run. See Section 3.1 for more details about the guarantee and what is checked.

The most important annotations supported by the Nullness Checker are `@NonNull` and `@Nullable`. `@NonNull` is rarely written, because it is the default. All of the annotations are explained in Section 3.2.

To run the Nullness Checker, supply the `-processor org.checkerframework.checker.nullness.NullnessChecker` command-line option to `javac`. For examples, see Section 3.5.

The `NullnessChecker` is actually an ensemble of three pluggable type-checkers that work together: the Nullness Checker proper (which is the main focus of this chapter), the Initialization Checker (Section 3.8), and the Map Key Checker (Chapter 4, page 48). Their type hierarchies are completely independent, but they work together to provide precise nullness checking.

3.1 What the Nullness Checker checks

The checker issues a warning in these cases:

1. When an expression of non-`@NonNull` type is dereferenced, because it might cause a null pointer exception. Dereferences occur not only when a field is accessed, but when an array is indexed, an exception is thrown, a lock is taken in a synchronized block, and more. For a complete description of all checks performed by the Nullness Checker, see the Javadoc for `NullnessVisitor`.
2. When an expression of `@NonNull` type might become null, because it is a misuse of the type: the null value could flow to a dereference that the checker does not warn about.
As a special case of an of `@NonNull` type becoming null, the checker also warns whenever a field of `@NonNull` type is not initialized in a constructor.

This example illustrates the programming errors that the checker detects:

```
@Nullable Object obj; // might be null
@NonNull Object nobj; // never null
...
obj.toString() // checker warning: dereference might cause null pointer exception
nobj = obj; // checker warning: nobj may become null
if (nobj == null) // checker warning: redundant test
```

Parameter passing and return values are checked analogously to assignments.

The Nullness Checker also checks the correctness, and correct use, of initialization (see Section 3.8) and of map key annotations (see Chapter 4, page 48).

The checker performs additional checks if certain `-Alint` command-line options are provided. (See Section 28.6 for more details about the `-Alint` command-line option.)

3.1.1 Nullness Checker optional warnings

1. Options that control soundness:

- If you supply the `-Alint=soundArrayCreationNullness` command-line option, then the checker warns if it encounters an array creation with a non-null component type. See Section 3.3.4 for a discussion.
- If you supply the `-Astubs=collection-object-parameters-may-be-null.astub` command-line option, then in JDK collection classes, the checker unsoundly permits null as an argument for any key or value formal parameter whose type is `Object` (instead of the element type). See Section 3.4.2.
- If you supply the `-Alint=trustArrayLenZero` command-line option, then the checker will trust `@ArrayLen(0)` annotations. See Section 3.3.5 for a discussion.

2. Options that warn about poor code style:

- If you supply the `-Alint=redundantNullComparison` command-line option, then the checker warns when a null check is performed against a value that is guaranteed to be non-null, as in `("m" == null)`. Such a check is unnecessary and might indicate a programmer error or misunderstanding. The lint option is disabled by default because sometimes such checks are part of ordinary defensive programming.

3.2 Nullness annotations

The Nullness Checker uses three separate type hierarchies: one for nullness, one for initialization (Section 3.8), and one for map keys (Chapter 4, page 48) The Nullness Checker has four varieties of annotations: nullness type qualifiers, nullness method annotations, initialization type qualifiers, and map key type qualifiers.

3.2.1 Nullness qualifiers

The nullness hierarchy contains these qualifiers:

@Nullable indicates a type that includes the null value. For example, the type `Boolean` is nullable: a variable of type `Boolean` always has one of the values `TRUE`, `FALSE`, or `null`.

@NonNull indicates a type that does not include the null value. The type `boolean` is non-null; a variable of type `boolean` always has one of the values `true` or `false`. The type `@NonNull Boolean` is also non-null: a variable of type `@NonNull Boolean` always has one of the values `TRUE` or `FALSE` — never `null`. Dereferencing an expression of non-null type can never cause a null pointer exception.

The `@NonNull` annotation is rarely written in a program, because it is the default (see Section 3.3.2).

@PolyNull indicates qualifier polymorphism. For a description of `@PolyNull`, see Section 26.2.

@MonotonicNonNull indicates a reference that may be null, but if it ever becomes non-null, then it never becomes null again. This is appropriate for lazily-initialized fields, for field initialization that occurs in a lifecycle method other than the constructor (e.g., an override of `android.app.Activity.onCreate`), and other uses. When the variable is read, its type is treated as `@Nullable`, but when the variable is assigned, its type is treated as `@NonNull`.

Because the Nullness Checker works intraprocedurally (it analyzes one method at a time), when a `MonotonicNonNull` field is first read within a method, the field cannot be assumed to be non-null. The benefit of `MonotonicNonNull` over `Nullable` is its different interaction with type refinement (Section 27.7). After a check of a `MonotonicNonNull` field, all subsequent accesses *within that method* can be assumed to be `NonNull`, even after arbitrary external method calls that have access to the given field.

It is permitted to initialize a `MonotonicNonNull` field to null, but the field may not be assigned to null anywhere else in the program. If you supply the `noInitForMonotonicNonNull` lint flag (for example, supply

Figure 3.1: Partial type hierarchy for the Nullness type system. Java’s `Object` is expressed as `@Nullable Object`. Programmers can omit most type qualifiers, because the default annotation (Section 3.3.2) is usually correct. The Nullness Checker verifies three type hierarchies: this one for nullness, one for initialization (Section 3.8), and one for map keys (Chapter 4, page 48).

-`Alint=noInitForMonotonicNonNull` on the command line), then `@MonotonicNonNull` fields are not allowed to have initializers at their declarations.

Use of `@MonotonicNonNull` on a static field is a code smell: it may indicate poor design. You should consider whether it is possible to make the field a member field that is set in the constructor.

Figure 3.1 shows part of the type hierarchy for the Nullness type system. (The annotations exist only at compile time; at run time, Java has no multiple inheritance.)

3.2.2 Nullness method annotations

The Nullness Checker supports several annotations that specify method behavior. These are declaration annotations, not type annotations: they apply to the method itself rather than to some particular type.

@RequiresNonNull indicates a method precondition: The annotated method expects the specified variables to be non-null when the method is invoked. Don’t use this for formal parameters (just annotate their type as `@NonNull`). `@RequiresNonNull` is appropriate for a field that is `@Nullable` in general, but some method requires the field to be non-null.

@EnsuresNonNull

@EnsuresNonNullIf indicates a method postcondition. With `@EnsuresNonNull`, the given expressions are non-null after the method returns; this is useful for a method that initializes a field, for example. With `@EnsuresNonNullIf`, if the annotated method returns the given boolean value (true or false), then the given expressions are non-null. See Section 3.3.3 and the Javadoc for examples of their use.

3.2.3 Initialization qualifiers

The Nullness Checker invokes an Initialization Checker, whose annotations indicate whether an object is fully initialized — that is, whether all of its fields have been assigned.

@Initialized

@UnknownInitialization

@UnderInitialization

Use of these annotations can help you to type-check more code. Figure 3.3 shows its type hierarchy. For details, see Section 3.8.

3.2.4 Map key qualifiers

@KeyFor

indicates that a value is a key for a given map — that is, indicates whether `map.containsKey(value)` would evaluate to `true`.

This annotation is checked by a Map Key Checker (Chapter 4, page 48) that the Nullness Checker invokes. The `@KeyFor` annotation enables the Nullness Checker to treat calls to `Map.get` precisely rather than assuming it may always return null. In particular, a call `mymap.get(mykey)` returns a non-null value if two conditions are satisfied:

1. `mymap`'s values are all non-null; that is, `mymap` was declared as `Map<KeyType, @NonNull ValueType>`. Note that `@NonNull` is the default type, so it need not be written explicitly.
2. `mykey` is a key in `mymap`; that is, `mymap.containsKey(mykey)` returns `true`. You express this fact to the Nullness Checker by declaring `mykey` as `@KeyFor("mymap") KeyType mykey`. For a local variable, you generally do not need to write the `@KeyFor("mymap")` type qualifier, because it can be inferred.

If either of these two conditions is violated, then `mymap.get(mykey)` has the possibility of returning null.

3.3 Writing nullness annotations

3.3.1 Implicit qualifiers

The Nullness Checker adds implicit qualifiers, reducing the number of annotations that must appear in your code (see Section 27.4). For example, enum types are implicitly non-null, so you never need to write `@NonNull MyEnumType`.

If you want details about implicitly-added nullness qualifiers, see the implementation of `NullnessAnnotatedTypeFactory`.

3.3.2 Default annotation

Unannotated references are treated as if they had a default annotation. The standard defaulting rule is CLIMB-to-top, described in Section 27.5.3. Its effect is to default all types to `@NonNull`, except that `@Nullable` is used for casts, locals, `instanceof`, and implicit bounds. A user can choose a different defaulting rule by writing a `@DefaultQualifier` annotation on a package, class, or method. In the example below, fields are defaulted to `@Nullable` instead of `@NonNull`.

```
@DefaultQualifier(value = Nullable.class, locations = TypeUseLocation.FIELD)
class MyClass {
    Object nullableField = null;
    @NonNull Object nonNullField = new Object();
}
```

3.3.3 Conditional nullness

The Nullness Checker supports a form of conditional nullness types, via the `@EnsuresNonNullIf` method annotations. The annotation on a method declares that some expressions are non-null, if the method returns true (false, respectively).

Consider `java.lang.Class`. Method `Class.getComponentType()` may return null, but it is specified to return a non-null value if `Class.isArray()` is true. You could declare this relationship in the following way (this particular example is already done for you in the annotated JDK that comes with the Checker Framework):

```
class Class<T> {
    @EnsuresNonNullIf(expression="getComponentType()", result=true)
    public native boolean isArray();

    public native @Nullable Class<?> getComponentType();
}
```

A client that checks that a `Class` reference is indeed that of an array, can then de-reference the result of `Class.getComponentType` safely without any nullness check. The Checker Framework source code itself uses such a pattern:

```

if (clazz.isArray()) {
    // no possible null dereference on the following line
    TypeMirror componentType = typeFromClass(clazz.getComponentType());
    ...
}

```

Another example is `Queue.peek` and `Queue.poll`, which return non-null if `isEmpty` returns false.

The argument to `@EnsuresNonNullIf` is a Java expression, including method calls (as shown above), method formal parameters, fields, etc.; for details, see Section 27.8. More examples of the use of these annotations appear in the Javadoc for `@EnsuresNonNullIf`.

3.3.4 Nullness and array initialization

Suppose that you declare an array to contain non-null elements:

```
Object [] oa = new Object[10];
```

(recall that `Object` means the same thing as `@NonNull Object`). By default, the Nullness Checker unsoundly permits this code.

To make the Nullness Checker conservatively reject code that may leave a non-null value in an array, use the command-line option `-Alint=soundArrayCreationNullness`. The option is currently disabled because it makes the checker issue many false positive errors.

With the option enabled, you can write your code to create a nullable or lazy-nonnull array, initialize each component, and then assign the result to a non-null array:

```

@MonotonicNonNull Object [] temp = new @MonotonicNonNull Object[10];
for (int i = 0; i < temp.length; ++i) {
    temp[i] = new Object();
}
@SuppressWarnings("nullness") // temp array is now fully initialized
@NonNull Object [] oa = temp;

```

Note that the checker is currently not powerful enough to ensure that each array component was initialized. Therefore, the last assignment needs to be trusted: that is, a programmer must verify that it is safe, then write a `@SuppressWarnings` annotation.

3.3.5 Nullness and conversions from collections to arrays

The semantics of `Collection.toArray(T[])` cannot be captured by the nullness type system syntax. The nullness type of the returned array depends on the size of the passed parameter. In particular, the returned array component is of type `@NonNull` if the following conditions hold:

- The receiver collection's type argument (that is, the element type) is `@NonNull`, and
- The passed array size is less than or equal to the collection size. The Nullness Checker uses these heuristics to handle the most common cases:
 - the argument has length 0:
 - * an empty array initializer, e.g. `c.toArray(new String[] {})`, or
 - * array creation tree of size 0, e.g. `c.toArray(new String[0])`.
 - array creation tree with a collection `size()` method invocation as argument `c.toArray(new String[c.size()])`.

Additionally, when you supply the `-Alint=trustArrayLenZero` command-line option, a call to `Collection.toArray` will be estimated to return an array with a non-null component type if the argument is a field access where the field declaration has a `@ArrayLen(0)` annotation. This trusts the `@ArrayLen(0)` annotation, but does not verify it. Run the Constant Value Checker (see Chapter 21, page 127) to verify that annotation.

Note: The nullness of the returned array doesn't depend on the passed array nullness. This is a fact about `Collection.toArray(T[])`, not a limitation of this heuristic.

3.3.6 Run-time checks for nullness

When you perform a run-time check for nullness, such as `if (x != null) ...`, then the Nullness Checker refines the type of `x` to `@NonNull`. The refinement lasts until the end of the scope of the test or until `x` may be side-effected. For more details, see Section 27.7.

3.3.7 Additional details

The Nullness Checker does some special checks in certain circumstances, in order to soundly reduce the number of warnings that it produces.

For example, a call to `System.getProperty(String)` can return null in general, but it will not return null if the argument is one of the built-in-keys listed in the documentation of `System.getProperties()`. The Nullness Checker is aware of this fact, so you do not have to suppress a warning for a call like `System.getProperty("line.separator")`. The warning is still issued for code like this:

```
final String s = "line.separator";
nonnullvar = System.getProperty(s);
```

though that case could be handled as well, if desired. (Suppression of the warning is, strictly speaking, not sound, because a library that your code calls, or your code itself, could perversely change the system properties; the Nullness Checker assumes this bizarre coding pattern does not happen.) (It is better style to use `System.lineSeparator()` than the call to `System.getProperty("line.separator")` anyway.)

3.3.8 Inference of `@NonNull` and `@Nullable` annotations

It can be tedious to write annotations in your code. Tools exist that can automatically infer annotations and insert them in your source code. (This is different than type qualifier refinement for local variables (Section 27.7), which infers a more specific type for local variables and uses them during type-checking but does not insert them in your source code. Type qualifier refinement is always enabled, no matter how annotations on signatures got inserted in your source code.)

Your choice of tool depends on what default annotation (see Section 3.3.2) your code uses. You only need one of these tools.

- Inference of `@Nullable`: If your code uses the standard CLIMB-to-top default (Section 27.5.3) or the `NonNull` default, then use the `AnnotateNullable` tool of the Daikon invariant detector.
- Inference of `@NonNull`: If your code uses the `Nullable` default, use one of these tools:
 - Julia analyzer,
 - Nit: Nullability Inference Tool,
 - Non-null checker and inferencer of the JastAdd Extensible Compiler.

3.4 Suppressing nullness warnings

When the Nullness Checker reports a warning, it's best to change the code or its annotations, to eliminate the warning. Alternately, you can suppress the warning, which does not change the code but prevents the Nullness Checker from reporting this particular warning to you.

The Checker Framework supplies several ways to suppress warnings, most notably the `@SuppressWarnings("nullness")` annotation (see Chapter 28). An example use is

```
// might return null
@Nullable Object getObject(...) { ... }

void myMethod() {
    @SuppressWarnings("nullness") // with argument x, getObject always returns a non-null value
    @NonNull Object o2 = getObject(x);
}
```

The Nullness Checker supports an additional warning suppression key, `nullness:generic.argument`. Use of `@SuppressWarnings("nullness:generic.argument")` causes the Nullness Checker to suppress warnings related to misuse of generic type arguments. One use for this key is when a class is declared to take only `@NonNull` type arguments, but you want to instantiate the class with a `@Nullable` type argument, as in `List<@Nullable Object>`.

The Nullness Checker also permits you to use assertions or method calls to suppress warnings; see below.

3.4.1 Suppressing warnings with assertions and method calls

Occasionally, it is inconvenient or verbose to use the `@SuppressWarnings` annotation. For example, Java does not permit annotations such as `@SuppressWarnings` to appear on statements. In such cases, you can use the `@AssumeAssertion` string in an `assert` message (see Section 28.2).

If you need to suppress a warning within an expression, then sometimes writing an assertion is not convenient. In such a case, you can suppress warnings by writing a call to the `NullnessUtil.castNonNull` method. The rest of this section discusses the `castNonNull` method.

The Nullness Checker considers both the return value, and also the argument, to be non-null after the `castNonNull` method call. The Nullness Checker issues no warnings in any of the following code:

```
// One way to use castNonNull as a cast:
@NonNull String s = castNonNull(possiblyNull1);

// Another way to use castNonNull as a cast:
castNonNull(possiblyNull2).toString();

// It is possible, but not recommended, to use castNonNull as a statement:
// (It would be better to write an assert statement with @AssumeAssertion
// in its message, instead.)
castNonNull(possiblyNull3);
possiblyNull3.toString();
```

The `castNonNull` method throws `AssertionError` if Java assertions are enabled and the argument is null. However, it is not intended for general defensive programming; see Section 28.2.1.

To use the `castNonNull` method, the `checker-qual.jar` file must be on the classpath at run time.

The Nullness Checker introduces a new method, rather than re-using an existing method such as `org.junit.Assert.assertNotNull(Object)` or `com.google.common.base.Preconditions.checkNotNull(Object)`. Those methods are commonly used for defensive programming, so it is impossible to know the programmer's intent when writing them. Therefore, it is important to have a method call that is used only for warning suppression. See Section 28.2.1 for a discussion of the distinction between warning suppression and defensive programming.

3.4.2 Null arguments to collection classes

For collection methods with `Object` formal parameter type, such as `contains`, `indexOf`, and `remove`, the annotated JDK forbids null as an argument.

The reason is that some implementations (like `ConcurrentHashMap`) throw `NullPointerException` if `null` is passed. It would be unsound to permit `null`, because it could lead to a false negative: the Checker Framework issuing no warning even though a `NullPointerException` can occur at run time.

However, many other common implementations permit such calls, so some users may wish to sacrifice soundness for a reduced number of false positive warnings. To permit `null` as an argument to these methods, pass the command-line argument `-Astubs=collection-object-parameters-may-be-null.astub`.

3.5 Examples

3.5.1 Tiny examples

To try the Nullness Checker on a source file that uses the `@NonNull` qualifier, use the following command (where `javac` is the Checker Framework compiler that is distributed with the Checker Framework):

```
javac -processor org.checkerframework.checker.nullness.NullnessChecker docs/examples/NullnessExample.java
```

Compilation will complete without warnings.

To see the checker warn about incorrect usage of annotations (and therefore the possibility of a null pointer exception at run time), use the following command:

```
javac -processor org.checkerframework.checker.nullness.NullnessChecker docs/examples/NullnessExampleWithWarnings.java
```

The compiler will issue two warnings regarding violation of the semantics of `@NonNull`.

3.5.2 Example annotated source code

Some libraries that are annotated with nullness qualifiers are:

- The Nullness Checker itself.
- The Java projects in the plume-lib GitHub organization. Type-checking occurs on each build.
- The Daikon invariant detector. Run the command `make check-nullness`.

3.6 Tips for getting started

Here are some tips about getting started using the Nullness Checker on a legacy codebase. For more generic advice (not specific to the Nullness Checker), see Section 2.4.2.

Your goal is to add `@Nullable` annotations to the types of any variables that can be null. (The default is to assume that a variable is non-null unless it has a `@Nullable` annotation.) Then, you will run the Nullness Checker. Each of its errors indicates either a possible null pointer exception, or a wrong/missing annotation. When there are no more warnings from the checker, you are done!

We recommend that you start by searching the code for occurrences of `null` in the following locations; when you find one, write the corresponding annotation:

- in Javadoc: add `@Nullable` annotations to method signatures (parameters and return types).
- `return null`: add a `@Nullable` annotation to the return type of the given method.
- `param == null`: when a formal parameter is compared to `null`, then in most cases you can add a `@Nullable` annotation to the formal parameter's type
- `TypeName field = null;`: when a field is initialized to `null` in its declaration, then it needs either a `@Nullable` or a `@MonotonicNonNull` annotation. If the field is always set to a non-null value in the constructor, then you can just change the declaration to `Type field;`, without an initializer, and write no type annotation (because the default is `@NonNull`).
- declarations of `contains`, `containsKey`, `containsValue`, `equals`, `get`, `indexOf`, `lastIndexOf`, and `remove` (with `Object` as the argument type): change the argument type to `@Nullable Object`; for `remove`, also change the return type to `@Nullable Object`.

You should ignore all other occurrences of `null` within a method body. In particular, you rarely need to annotate local variables (except their type arguments or array element types).

Only after this step should you run the Nullness Checker. The reason is that it is quicker to search for places to change than to repeatedly run the checker and fix the errors it tells you about, one at a time.

Here are some other tips:

- In any file where you write an annotation such as `@Nullable`, don't forget to add `import org.checkerframework.checker.nullness.qual.*;`
- To indicate an array that can be null, write, for example: `int @Nullable []`.
By contrast, `@Nullable Object []` means a non-null array that contains possibly-null objects.
- If you know that a particular variable is definitely not null, but the Nullness Checker estimates that the variable might be null, then you can make the Nullness Checker trust your judgment by writing an assertion (see Section 28.2):

```
assert var != null : "@AssumeAssertion(nullness)";
```
- To indicate that a routine returns the same value every time it is called, use `@Pure` (see Section 27.7.5).
- To indicate a method precondition (a contract stating the conditions under which a client is allowed to call it), you can use annotations such as `@RequiresNonNull` (see Section 3.2.2).

3.7 Other tools for nullness checking

The Checker Framework's nullness annotations are similar to annotations used in other tools. You might prefer to use the Checker Framework because it has a more powerful analysis that can warn you about more null pointer errors in your code. Most of the other tools are bug-finding tools rather than verification tools, since they give up precision, soundness, or both in favor of being fast and easy to use. Also see Section 34.10.1 for a comparison to other tools.

If your code is already annotated with a different nullness annotation, the Checker Framework can type-check your code. It treats annotations from other tools as if you had written the corresponding annotation from the Nullness Checker, as described in Figure 3.2. If the other annotation is a declaration annotation, it may be moved; see Section 29.1.1.

The Checker Framework may issue more or fewer errors than another tool. This is expected, since each tool uses a different analysis. Remember that the Checker Framework aims at soundness: it aims to never miss a possible null dereference, while at the same time limiting false reports. Also, note FindBugs's non-standard meaning for `@Nullable` (Section 3.7.2).

Java permits you to import at most one annotation of a given name. For example, if you use both `android.annotation.NonNull` and `lombok.NonNull` in your source code, then you must write at least one of them in fully-qualified form, as `@android.annotation.NonNull` rather than as `@NonNull`.

3.7.1 Which tool is right for you?

Different tools are appropriate in different circumstances. Here is a brief comparison with FindBugs, but similar points apply to other tools. (For example, the NullAway and Eradicate tools are more like sound type-checking than FindBugs, but all of those tools accept unsoundness — that is, false negatives or missed warnings — in exchange for analysis speed.)

The Checker Framework has a more powerful nullness analysis; FindBugs misses some real errors. FindBugs requires you to annotate your code, but usually not as thoroughly as the Checker Framework does. Depending on the importance of your code, you may desire: no nullness checking, the cursory checking of FindBugs, or the thorough checking of the Checker Framework. You might even want to ensure that both tools run, for example if your coworkers or some other organization are still using FindBugs. If you know that you will eventually want to use the Checker Framework, there is no point using FindBugs first; it is easier to go straight to using the Checker Framework.

FindBugs can find other errors in addition to nullness errors; here we focus on its nullness checks. Even if you use FindBugs for its other features, you may want to use the Checker Framework for analyses that can be expressed as pluggable type-checking, such as detecting nullness errors.

Figure 3.2: Correspondence between other nullness annotations and the Checker Framework’s annotations.

Regardless of whether you wish to use the FindBugs nullness analysis, you may continue running all of the other FindBugs analyses at the same time as the Checker Framework; there are no interactions among them.

If FindBugs (or any other tool) discovers a nullness error that the Checker Framework does not, please report it to us (see Section 35.2) so that we can enhance the Checker Framework.

3.7.2 Incompatibility note about FindBugs @Nullable

FindBugs has a non-standard definition of @Nullable. FindBugs's treatment is not documented in its own Javadoc; it is different from the definition of @Nullable in every other tool for nullness analysis; it means the same thing as @NonNull when applied to a formal parameter; and it invariably surprises programmers. Thus, FindBugs's @Nullable is detrimental rather than useful as documentation. In practice, your best bet is to not rely on FindBugs for nullness analysis, even if you find FindBugs useful for other purposes.

You can skip the rest of this section unless you wish to learn more details.

FindBugs suppresses all warnings at uses of a @Nullable variable. (You have to use @CheckForNull to indicate a nullable variable that FindBugs should check.) For example:

```
// declare getObject() to possibly return null
@Nullable Object getObject() { ... }

void myMethod() {
    @Nullable Object o = getObject();
    // FindBugs issues no warning about calling toString on a possibly-null reference!
    o.toString();
}
```

The Checker Framework does not emulate this non-standard behavior of FindBugs, even if the code uses FindBugs annotations.

With FindBugs, you annotate a declaration, which suppresses checking at *all* client uses, even the places that you want to check. It is better to suppress warnings at only the specific client uses where the value is known to be non-null; the Checker Framework supports this, if you write @SuppressWarnings at the client uses. The Checker Framework also supports suppressing checking at all client uses, by writing a @SuppressWarnings annotation at the declaration site. Thus, the Checker Framework supports both use cases, whereas FindBugs supports only one and gives the programmer less flexibility.

In general, the Checker Framework will issue more warnings than FindBugs, and some of them may be about real bugs in your program. See Section 3.4 for information about suppressing nullness warnings.

(FindBugs made a poor choice of names. The choice of names should make a clear distinction between annotations that specify whether a reference is null, and annotations that suppress false warnings. The choice of names should also have been consistent for other tools, and intuitively clear to programmers. The FindBugs choices make the FindBugs annotations less helpful to people, and much less useful for other tools. As a separate issue, the FindBugs analysis is also very imprecise. For type-related analyses, it is best to stay away from the FindBugs nullness annotations, and use a more capable tool like the Checker Framework.)

3.7.3 Relationship to Optional<T>

Many null pointer exceptions occur because the programmer forgets to check whether a reference is null before dereferencing it. Java 8's Optional<T> class provides a partial solution: a programmer must call the get method to access the value, and the designers of Optional hope that the syntactic occurrence of the get method will remind programmers to first check that the value is present. This is still easy to forget, however.

The Checker Framework contains an Optional Checker (see Chapter 5) that guarantees that programmers use Optional correctly, such as calling isPresent before calling get.

There are some limitations to the utility of Optional, which might lead to you choose to use regular Java references rather than Optional. (For more details, see the article “Nothing is better than the Optional type”.)

- It is still possible to call `get` on a non-present `Optional`, leading to a `NoSuchElementException`. In other words, `Optional` doesn't solve the underlying problem — it merely converts a `NullPointerException` into a `NoSuchElementException` exception, and in either case your code crashes.
- `NullPointerException` is still possible in code that uses `Optional`.
- `Optional` adds syntactic complexity, making your code longer and harder to read.
- `Optional` adds time and space overhead.
- `Optional` does not address important sources of null pointer exceptions, such as partially-initialized objects and calls to `Map.get`.

The Nullness Checker does not suffer these limitations. Furthermore, it works with existing code and types, it ensures that you check for null wherever necessary, and it infers when the check for null is not necessary based on previous statements in the method.

Java's `Optional` class provides utility routines to reduce clutter when using `Optional`. The Nullness Checker provides an `Opt` class that provides all the same methods, but written for regular possibly-null Java references.

3.8 Initialization Checker

The Initialization Checker determines whether an object is initialized or not. For any object that is not fully initialized, the Nullness Checker treats its fields as possibly-null — even fields annotated as `@NonNull`.

Every object's fields start out as null. By the time the constructor finishes executing, the `@NonNull` fields have been set to a different value. Your code can suffer a `NullPointerException` when using a `@NonNull` field, if your code uses the field during initialization. The Nullness Checker prevents this problem by warning you anytime that you may be accessing an uninitialized field. This check is useful because it prevents errors in your code. However, the analysis can be confusing to understand. If you wish to disable the initialization checks, see Section 3.8.8.

An object is partially initialized from the time that its constructor starts until its constructor finishes. This is relevant to the Nullness Checker because while the constructor is executing — that is, before initialization completes — a `@NonNull` field may be observed to be null, until that field is set. In particular, the Nullness Checker issues a warning for code like this:

```
public class MyClass {
    private @NonNull Object f;
    public MyClass(int x) {
        // Error because constructor contains no assignment to this.f.
        // By the time the constructor exits, f must be initialized to a non-null value.
    }
    public MyClass(int x, int y) {
        // Error because this.f is accessed before f is initialized.
        // At the beginning of the constructor's execution, accessing this.f
        // yields null, even though field f has a non-null type.
        this.f.toString();
        f = new Object();
    }
    public MyClass(int x, int y, int z) {
        m();
        f = new Object();
    }
    public void m() {
        // Error because this.f is accessed before f is initialized,
        // even though the access is not in a constructor.
        // When m is called from the constructor, accessing f yields null,
        // even though field f has a non-null type.
    }
}
```

Figure 3.3: Partial type hierarchy for the Initialization type system. `@UnknownInitialization` and `@UnderInitialization` each take an optional parameter indicating how far initialization has proceeded, and the right side of the figure illustrates its type hierarchy in more detail.

```

    this.f.toString();
}

```

When a field `f` is declared with a `@NonNull` type, then code can depend on the fact that the field is not `null`. However, this guarantee does not hold for a partially-initialized object.

The Nullness Checker uses three annotations to indicate whether an object is initialized (all its `@NonNull` fields have been assigned), under initialization (its constructor is currently executing), or its initialization state is unknown.

These distinctions are mostly relevant within the constructor, or for references to `this` that escape the constructor (say, by being stored in a field or passed to a method before initialization is complete). Use of initialization annotations is rare in most code.

3.8.1 Initialization qualifiers

The initialization hierarchy is shown in Figure 3.3. The initialization hierarchy contains these qualifiers:

@Initialized indicates a type that contains a fully-initialized object. `Initialized` is the default, so there is little need for a programmer to write this explicitly.

@UnknownInitialization indicates a type that may contain a partially-initialized object. In a partially-initialized object, fields that are annotated as `@NonNull` may be `null` because the field has not yet been assigned.

`@UnknownInitialization` takes a parameter that is the class the object is definitely initialized up to. For instance, the type `@UnknownInitialization(Foo.class)` denotes an object in which every fields declared in `Foo` or its superclasses is initialized, but other fields might not be. Just `@UnknownInitialization` is equivalent to `@UnknownInitialization(Object.class)`.

@UnderInitialization indicates a type that contains a partially-initialized object that is under initialization — that is, its constructor is currently executing. It is otherwise the same as `@UnknownInitialization`. Within the constructor, `this` has `@UnderInitialization` type until all the `@NonNull` fields have been assigned.

A partially-initialized object (`this` in a constructor) may be passed to a helper method or stored in a variable; if so, the method receiver, or the field, would have to be annotated as `@UnknownInitialization` or as `@UnderInitialization`.

If a reference has `@UnknownInitialization` or `@UnderInitialization` type, then all of its `@NonNull` fields are treated as `@MonotonicNonNull`: when read, they are treated as being `@Nullable`, but when written, they are treated as being `@NonNull`.

The initialization hierarchy is orthogonal to the nullness hierarchy. It is legal for a reference to be `@NonNull @UnderInitialization`, `@Nullable @UnderInitialization`, `@NonNull @Initialized`, or `@Nullable @Initialized`. The nullness hierarchy tells you about the reference itself: might the reference be `null`? The initialization hierarchy tells you about the `@NonNull` fields in the referred-to object: might those fields be temporarily `null` in contravention of their type annotation? Figure 3.4 contains some examples.

Declarations	Expression	Expression's nullness type, or checker error
<pre>class C { @NonNull Object f; @Nullable Object g; ... } @NonNull @Initialized C a;</pre>	<pre>a a.f a.g</pre>	<pre>@NonNull @NonNull @Nullable</pre>
<pre>@NonNull @UnderInitialization C b;</pre>	<pre>b b.f b.g</pre>	<pre>@NonNull @MonotonicNonNull @Nullable</pre>
<pre>@Nullable @Initialized C c;</pre>	<pre>c c.f c.g</pre>	<pre>@Nullable error: deref of nullable error: deref of nullable</pre>
<pre>@Nullable @UnderInitialization C d;</pre>	<pre>d d.f d.g</pre>	<pre>@Nullable error: deref of nullable error: deref of nullable</pre>

Figure 3.4: Examples of the interaction between nullness and initialization. Declarations are shown at the left for reference, but the focus of the table is the expressions and their nullness type or error.

3.8.2 How an object becomes initialized

Within the constructor, this starts out with `@UnderInitialization` type. As soon as all of the `@NonNull` fields in class `C` have been initialized, then this is treated as `@UnderInitialization(C)`. This means that this is still being initialized, but all initialization of `C`'s fields is complete, including all fields of supertypes. Eventually, when all constructors complete, the type is `@Initialized`.

The Initialization Checker issues an error if the constructor fails to initialize any `@NonNull` field. This ensures that the object is in a legal (initialized) state by the time that the constructor exits. This is different than Java's test for definite assignment (see JLS ch.16), which does not apply to fields (except blank final ones, defined in JLS §4.12.4) because fields have a default value of null.

All `@NonNull` fields must either have a default in the field declaration, or be assigned in the constructor or in a helper method that the constructor calls. If your code initializes (some) fields in a helper method, you will need to annotate the helper method with an annotation such as `@EnsuresNonNull({"field1", "field2"})` for all the fields that the helper method assigns.

3.8.3 @UnderInitialization examples

The most common use for the `@UnderInitialization` annotation is for a helper routine that is called by constructor. For example:

```
class MyClass {
  Object field1;
  Object field2;
  Object field3;

  public MyClass(String arg1) {
    this.field1 = arg1;
    init_other_fields();
  }
}
```

```

// A helper routine that initializes all the fields other than field1.
@EnsuresNonNull({"field2", "field3"})
private void init_other_fields(@UnderInitialization(Object.class) MyClass this) {
    field2 = new Object();
    field3 = new Object();
}

public MyClass(String arg1, String arg2, String arg3) {
    this.field1 = arg1;
    this.field2 = arg2;
    this.field3 = arg3;
    checkRep();
}

// Verify that the representation invariants are satisfied.
// Works as long as the MyClass fields are initialized, even if the receiver's
// class is a subclass of MyClass and not all of the subclass fields are initialized.
private void checkRep(@UnderInitialization(MyClass.class) MyClass this) {
    ...
}
}

```

At the end of the constructor, this is not fully initialized. Rather, it is `@UnderInitialization(CurrentClass.class)`. The reason is that there might be subclasses with uninitialized fields. The following example illustrates this:

```

class A {
    @NonNull String a;
    public A() {
        a = "";
        // Now, all fields of A are initialized.
        // However, if this constructor is invoked as part of 'new B()', then
        // the fields of B are not yet initialized.
        // If we would type 'this' as @Initialized, then the following call is valid:
        doSomething();
    }
    void doSomething() {}
}

class B extends A {
    @NonNull String b;
    @Override
    void doSomething() {
        // Dereferencing 'b' is ok, because 'this' is @Initialized and 'b' @NonNull.
        // However, when executing 'new B()', this line throws a null-pointer exception.
        b.toString();
    }
}
}

```

3.8.4 Partial initialization

So far, we have discussed initialization as if it is an all-or-nothing property: an object is non-initialized until initialization completes, and then it is initialized. The full truth is a bit more complex: during the initialization process an object can be partially initialized, and as the object's superclass constructors complete, its initialization status is updated. The Initialization Checker lets you express such properties when necessary.

Consider a simple example:

```
class A {
    Object aField;
    A() {
        aField = new Object();
    }
}
class B extends A {
    Object bField;
    B() {
        super();
        bField = new Object();
    }
}
```

Consider what happens during execution of `new B()`.

1. B's constructor begins to execute. At this point, neither the fields of A nor those of B have been initialized yet.
2. B's constructor calls A's constructor, which begins to execute. No fields of A nor of B have been initialized yet.
3. A's constructor completes. Now, all the fields of A have been initialized, and their invariants (such as that field a is non-null) can be depended on. However, because B's constructor has not yet completed executing, the object being constructed is not yet fully initialized. When treated as an A (e.g., if only the A fields are accessed), the object is initialized, but when treated as a B, the object is still non-initialized.
4. B's constructor completes. The object is initialized when treated as an A or a B. (And, the object is fully initialized if B's constructor was invoked via a `new B()`. But the type system cannot assume that — there might be a class `C extends B { ... }`, and B's constructor might have been invoked from that.)

At any moment during initialization, the superclasses of a given class can be divided into those that have completed initialization and those that have not yet completed initialization. More precisely, at any moment there is a point in the class hierarchy such that all the classes above that point are fully initialized, and all those below it are not yet initialized. As initialization proceeds, this dividing line between the initialized and uninitialized classes moves down the type hierarchy.

The Nullness Checker lets you indicate where the dividing line is between the initialized and non-initialized classes. The `@UnderInitialization(classLiteral)` indicates the first class that is known to be fully initialized. When you write `@UnderInitialization(OtherClass.class) MyClass x;`, that means that variable `x` is initialized for `OtherClass` and its superclasses, and `x` is (possibly) uninitialized for `MyClass` and all subclasses.

The example above lists 4 moments during construction. At those moments, the type of the object being constructed is:

1. `@UnderInitialization B`
2. `@UnderInitialization A`
3. `@UnderInitialization(A.class) A`
4. `@UnderInitialization(B.class) B`

3.8.5 Method calls from the constructor

Consider the following incorrect program.

```

class A {
    Object aField;
    A() {
        aField = new Object();
        process(5); // illegal call
    }
    public void process(int arg) { ... }
}

```

The call to `process()` is not legal. `process()` is declared to be called on a fully-initialized receiver, which is the default if you do not write a different initialization annotation. At the call to `process()`, all the fields of `A` have been set, but this is not fully initialized because fields in subclasses of `A` have not yet been set. The type of this is `@UnderInitialization(A.class)`, meaning that this is partially-initialized, with the `A` part of initialization done but the initialization of subclasses not yet complete.

The Initialization Checker output indicates this problem:

```

Client.java:7: error: [method.invocation.invalid] call to process(int) not allowed on the given receiver.
    process(5); // illegal call
        ^
found   : @UnderInitialization(A.class) A
required: @Initialized A

```

Here is a subclass and client code that crashes with a `NullPointerException`.

```

class B extends A {
    List<Integer> processed;
    B() {
        super();
        processed = new ArrayList<Integer>();
    }
    @Override
    public void process(int arg) {
        super();
        processed.add(arg);
    }
}
class Client {
    public static void main(String[] args) {
        new B();
    }
}

```

You can correct the problem in multiple ways.

One solution is to not call methods that can be overridden from the constructor: move the call to `process()` to after the constructor has completed.

Another solution is to change the declaration of `process()`:

```

public void process(@UnderInitialization(A.class) A this, int arg) { ... }

```

If you choose this solution, you will need to rewrite the definition of `B.process()` so that it is consistent with the declared receiver type.

A non-solution is to prevent subclasses from overriding `process()` by using `final` on the method. This doesn't work because even if `process()` is not overridden, it might call other methods that are overridden.

As `final` classes cannot have subclasses, they can be handled more flexibly: once all fields of the final class have been initialized, this is fully initialized.

x.f	f is @NonNull	f is @Nullable
x is @Initialized	@Initialized @NonNull	@Initialized @Nullable
x is @UnderInitialization	@UnknownInitialization @Nullable	@UnknownInitialization @Nullable
x is @UnknownInitialization	@UnknownInitialization @Nullable	@UnknownInitialization @Nullable

Figure 3.5: Initialization rules for reading a @NotOnlyInitialized field f.

x.f = y	y is @Initialized	y is @UnderInitialization	y is @UnknownInitialization
x is @Initialized	yes	no	no
x is @UnderInitialization	yes	yes	yes
x is @UnknownInitialization	yes	no	no

Figure 3.6: Rules for deciding when an assignment x.f = y is allowed for a @NotOnlyInitialized field f.

3.8.6 Initialization of circular data structures

There is one final aspect of the initialization type system to be considered: the rules governing reading and writing to objects that are currently under initialization (both reading from fields of objects under initialization, as well as writing objects under initialization to fields). By default, only fully-initialized objects can be stored in a field of another object. If this was the only option, then it would not be possible to create circular data structures (such as a doubly-linked list) where fields have a @NonNull type. However, the annotation @NotOnlyInitialized can be used to indicate that a field can store objects that are currently under initialization. In this case, the rules for reading and writing to that field become a little bit more interesting, to soundly support circular structures.

The rules for reading from a @NotOnlyInitialized field are summarized in Figure 3.5. Essentially, nothing is known about the initialization status of the value returned unless the receiver was @Initialized.

Similarly, Figure 3.6 shows under which conditions an assignment x.f = y is allowed for a @NotOnlyInitialized field f. If the receiver x is @UnderInitialization, then any y can be of any initialization state. If y is known to be fully initialized, then any receiver is allowed. All other assignments are disallowed.

These rules allow for the safe initialization of circular structures. For instance, consider a doubly linked list:

```
class List<T> {
    @NotOnlyInitialized
    Node<T> sentinel;

    public List() {
        this.sentinel = new Node<>(this);
    }

    void insert(@Nullable T data) {
        this.sentinel.insertAfter(data);
    }

    public static void main() {
        List<Integer> l = new List<>();
        l.insert(1);
        l.insert(2);
    }
}

class Node<T> {
    @NotOnlyInitialized
    Node<T> prev;
}
```

```

@NotNull
Node<T> next;

@NotNull
List parent;

@Nullable
T data;

// for sentinel construction
Node(@UnderInitialization List parent) {
    this.parent = parent;
    this.prev = this;
    this.next = this;
}

// for data node construction
Node(Node<T> prev, Node<T> next, @Nullable T data) {
    this.parent = prev.parent;
    this.prev = prev;
    this.next = next;
    this.data = data;
}

void insertAfter(@Nullable T data) {
    Node<T> n = new Node<>(this, this.next, data);
    this.next.prev = n;
    this.next = n;
}
}

```

3.8.7 How to handle warnings

“error: the constructor does not initialize fields: ...”

Like any warning, “error: the constructor does not initialize fields: ...” indicates that either your annotations are incorrect or your code is buggy. You can fix either the annotations or the code.

- Declare the field as `@Nullable`. Recall that if you did not write an annotation, the field defaults to `@NonNull`.
- Declare the field as `@MonotonicNonNull`. This is appropriate if the field starts out as `null` but is later set to a non-null value. You may then wish to use the `@EnsuresNonNull` annotation to indicate which methods set the field, and the `@RequiresNonNull` annotation to indicate which methods require the field to be non-null.
- Initialize the field in the constructor or in the field’s initializer, if the field should be initialized. (In this case, the Initialization Checker has found a bug!)

Do *not* initialize the field to an arbitrary non-null value just to eliminate the warning. Doing so degrades your code: it introduces a value that will confuse other programmers, and it converts a clear `NullPointerException` into a more obscure error.

“call to ... is not allowed on the given receiver”

If your code calls an instance method from a constructor, you may see a message such as the following:

```

MyFile.java:123: error: call to initHelper() not allowed on the given receiver.
    initHelper();
      ^
found   : @UnderInitialization(com.google.Bar.class) @NonNull MyClass
required: @Initialized @NonNull MyClass

```

The problem is that the current object (`this`) is under initialization, but the receiver formal parameter (Section 34.6.1) of method `initHelper()` is implicitly annotated as `@Initialized`. If `initHelper()` doesn't depend on its receiver being initialized — that is, it's OK to call `x.initHelper` even if `x` is not initialized — then you can indicate that by using `@UnderInitialization` or `@UnknownInitialization`.

```

class MyClass {
    void initHelper(@UnknownInitialization MyClass this, String param1) { ... }
}

```

You are likely to want to annotate `initHelper()` with `@EnsuresNonNull` as well; see Section 3.2.2.

You may get the “call to ... is not allowed on the given receiver” error even if your constructor has already initialized all the fields. For this code:

```

public class MyClass {
    @NonNull Object field;
    public MyClass() {
        field = new Object();
        helperMethod();
    }
    private void helperMethod() {
    }
}

```

the Nullness Checker issues the following warning:

```

MyClass.java:7: error: call to helperMethod() not allowed on the given receiver.
    helperMethod();
      ^
found   : @UnderInitialization(MyClass.class) @NonNull MyClass
required: @Initialized @NonNull MyClass
1 error

```

The reason is that even though the object under construction has had all the fields declared in `MyClass` initialized, there might be a subclass of `MyClass`. Thus, the receiver of `helperMethod` should be declared as `@UnderInitialization(MyClass.class)`, which says that initialization has completed for all the `MyClass` fields but may not have been completed overall. If `helperMethod` had been a public method that could also be called after initialization was actually complete, then the receiver should have type `@UnknownInitialization`, which is the supertype of `@UnknownInitialization` and `@UnderInitialization`.

3.8.8 Suppressing warnings

To suppress most warnings related to partially-initialized values, use the “initialization.” (note the trailing period) warning suppression key. You can write `@SuppressWarnings("initialization.")` on a field, constructor, or class, or pass the command-line argument `-AsuppressWarnings=initialization.` when running the Nullness Checker. (For more about suppressing warnings, see Chapter 28, page 171). You will no longer get a guarantee of no null pointer exceptions, but you can still use the Nullness Checker to find most of the null pointer problems in your code.

This suppresses warnings that are specific to the Initialization Checker, but does not suppress warnings issued by the Checker Framework itself, such as about assignments or method overriding.

It is not possible to completely disable initialization checking while retaining nullness checking. The “initialization” warning suppression key (without a period) has the same effect as the “nullness” key: both of them disable all nullness and initialization checking. That is because of an implementation detail of the Nullness and Initialization Checkers: they are actually the same checker, rather than being two separate checkers that are aggregated together.

3.8.9 More details about initialization checking

Use of method annotations A method with a non-initialized receiver may assume that a few fields (but not all of them) are non-null, and it sometimes sets some more fields to non-null values. To express these concepts, use the `@RequiresNonNull`, `@EnsuresNonNull`, and `@EnsuresNonNullIf` method annotations; see Section 3.2.2.

Source of the type system The type system enforced by the Initialization Checker is based on “Freedom Before Commitment” [SM11]. Our implementation changes its initialization modifiers (“committed”, “free”, and “unclassified”) to “initialized”, “unknown initialization”, and “under initialization”. Our implementation also has several enhancements. For example, it supports partial initialization (the argument to the `@UnknownInitialization` and `@UnderInitialization` annotations). The benefit (in terms of reduced false positive initialization warnings) from supporting partial initialization is greater than the benefit from adopting the Freedom Before Commitment system.

Chapter 4

Map Key Checker

The Map Key Checker tracks which values are keys for which maps. If variable `v` has type `@KeyFor("m") . . .`, then the value of `v` is a key in Map `m`. That is, the expression `m.containsKey(v)` evaluates to `true`.

Section 3.2.4 describes how `@KeyFor` annotations enable the Nullness Checker (Chapter 3, page 27) to treat calls to `Map.get` more precisely by refining its result to `@NonNull` in some cases.

You will not typically run the Map Key Checker. It is automatically run by other checkers, in particular the Nullness Checker.

You can unsoundly suppress warnings related to map keys with `@SuppressWarnings("keyfor")`, or everywhere by using command-line option `-AsuppressWarnings=keyfor`; see Chapter 28, page 171.

4.1 Map key annotations

These qualifiers are part of the Map Key type system:

@KeyFor(String[] maps) indicates that the value assigned to the annotated variable is a key for at least the given maps.

@UnknownKeyFor is used internally by the type system but should never be written by a programmer. It indicates that the value assigned to the annotated variable is not known to be a key for any map. It is the default type qualifier.

@KeyForBottom is used internally by the type system but should never be written by a programmer. There are no values of this type (not even `null`).

The following method annotations can be used to establish a method postcondition that ensures that a certain expression is a key for a map:

@EnsuresKeyFor(String[] value, String[] map) When the method with this annotation returns, the expression (or all the expressions) given in the `value` element is a key for the given maps. More precisely, the expression has the `@KeyFor` qualifier with the `value` arguments taken from the `targetValue` element of this annotation.

@EnsuresKeyForIf(String[] expression, boolean result, String[] map) If the method with this annotation returns the given boolean value, then the given expression (or all the given expressions) is a key for the given maps.

4.2 Default annotations

The qualifier for the type of the `null` literal is `@UnknownKeyFor`. If `null` were `@KeyForBottom`, that would mean that `null` is guaranteed to be a key for every map (which is not necessarily true).

Figure 4.1: The subtyping relationship of the Map Key Checker’s qualifiers. `@KeyFor(A)` is a supertype of `@KeyFor(B)` if and only if `A` is a subset of `B`. Qualifiers in gray are used internally by the type system but should never be written by a programmer.

4.2.1 Default for lower bounds

Lower bounds are defaulted to `@UnknownKeyFor`. However, in `java.*` packages, the default for lower bounds is `@KeyForBottom`.

It is challenging to choose a default for lower bounds of type variables and wildcards.

Here is a comparison of two choices for lower bounds:

<code>@KeyForBottom</code> default	<code>@UnknownKeyFor</code> default (current choice)
<code>class MyClass1<@UnknownKeyFor T> {</code> <code>T var = null; // OK</code>	<code>class MyClass1<T> {</code> <code>T var = null; // OK</code>
<code>class MyClass2<T> {</code> <code>@UnknownKeyFor T var = null; // OK</code>	
<code>class MyClass3<T> {</code> <code>T var = null; // ERROR</code>	
	<code>class MySet1<T> implements Set<T> { }</code> <code>MySet1<@KeyFor("m") String> s1; // ERROR</code>
<code>class Set<E> { }</code> <code>class MySet2<T> implements Set<T> { }</code> <code>MySet2<@KeyFor("m") String> s2; // OK</code>	<code>class Set<@KeyForBottom E> { }</code> <code>class MySet2<@KeyForBottom T> implements Set<T> { }</code> <code>MySet2<@KeyFor("m") String> s2; // OK</code>

If lower bounds are defaulted to `@KeyForBottom` (which is not currently the case), then whenever `null` is assigned to a variable whose type is a type variable, programmers must write an `@UnknownKeyFor` annotation on either the type variable declaration or on variable declarations, as shown in `MyClass1` and `MyClass2`. A disadvantage of this default is that the Map Key checker may issue warnings in code that has nothing to do with map keys, and in which no map key annotations are used.

If lower bounds are defaulted to `@UnknownKeyFor` (which is currently the case), then whenever a client might use a `@KeyFor` type argument, programmers must write a `@KeyForBottom` annotation on the type parameter, as in `MySet2` (and `Set`).

4.2.2 Diagnosing the need for explicit `@KeyFor` on lower bounds

Under the current defaulting (lower bounds default to `@UnknownKeyFor`), suppose you write this code:

```
public class Graph<N> {
    Map<N, Integer> nodes = new HashMap<>();
}
```

```
class Client {
    @Nullable Graph<@KeyFor("g.nodes") String> g;
}
```

The Nullness Checker issues this error message:

```
Graph.java:14: error: [type.argument.type.incompatible] incompatible types in type argument.
    @Nullable Graph<@KeyFor("g.nodes") String> g;
                    ^
    found   : @KeyFor("this.g.nodes") String
    required: [extends @UnknownKeyFor Object super @UnknownKeyFor null]
```

Note that the upper and lower bounds are both `@UnknownKeyFor`. You can make the code type-check by writing a lower bound, which is written before the type variable name (Section 26.1.2):

```
public class Graph<@KeyForBottom N> {
    ...
}
```

4.3 Examples

The Map Key Checker keeps track of which variables reference keys to which maps. A variable annotated with `@KeyFor(mapSet)` can only contain a value that is a key for all the maps in *mapSet*. For example:

```
Map<String,Date> m, n;
@KeyFor("m") String km;
@KeyFor("n") String kn;
@KeyFor({"m", "n"}) String kmn;
km = kmn;    // OK - a key for maps m and n is also a key for map m
kn = kmn;    // error: a key for map n is not necessarily a key for map m
```

As with any annotation, use of the `@KeyFor` annotation may force you to slightly refactor your code. For example, this would be illegal:

```
Map<String,Object> m;
Collection<@KeyFor("m") String> coll;
coll.add(x);    // error: element type is @KeyFor("m") String, but x does not have that type
m.put(x, ...);
```

The example type-checks if you reorder the two calls:

```
Map<String,Object> m;
Collection<@KeyFor("m") String> coll;
m.put(x, ...);    // after this statement, x has type @KeyFor("m") String
coll.add(x);    // OK
```

4.4 Inference of `@KeyFor` annotations

Within a method body, you usually do not have to write `@KeyFor` explicitly (except sometimes on type arguments), because the checker infers it based on usage patterns. When the Map Key Checker encounters a run-time check for map keys, such as “`if (m.containsKey(k)) ...`”, then the Map Key Checker refines the type of `k` to `@KeyFor("m")` within the scope of the test (or until `k` is side-effected within that scope). The Map Key Checker also infers `@KeyFor` annotations based on iteration over a map’s key set or calls to `put` or `containsKey`. For more details about type refinement, see Section 27.7.

Suppose we have these declarations:

```
Map<String,Date> m = new Map<>();
String k = "key";
@KeyFor("m") String km;
```

Ordinarily, the following assignment does not type-check:

```
km = k;    // Error since k is not known to be a key for map m.
```

The following examples show cases where the Map Key Checker infers a `@KeyFor` annotation for variable `k` based on usage patterns, enabling the `km = k` assignment to type-check.

```
m.put(k, ...);
// At this point, the type of k is refined to @KeyFor("m") String.
km = k;    // OK
```

```
if (m.containsKey(k)) {
    // At this point, the type of k is refined to @KeyFor("m") String.
    km = k;    // OK
    ...
} else {
    km = k;    // Error since k is not known to be a key for map m.
    ...
}
```

The following example shows a case where the Map Key Checker resets its assumption about the type of a field used as a key because that field may have been side-effected.

```
class MyClass {
    private Map<String,Object> m;
    private String k;    // The type of k defaults to @UnknownKeyFor String
    private @KeyFor("m") String km;

    public void myMethod() {
        if (m.containsKey(k)) {
            km = k;    // OK: the type of k is refined to @KeyFor("m") String

            sideEffectFreeMethod();
            km = k;    // OK: the type of k is not affected by the method call
                       // and remains @KeyFor("m") String

            otherMethod();
            km = k;    // error: At this point, the type of k is once again
                       // @UnknownKeyFor String, because otherMethod might have
                       // side-effected k such that it is no longer a key for map m.
        }
    }

    @SideEffectFree
    private void sideEffectFreeMethod() { ... }

    private void otherMethod() { ... }
}
```

Chapter 5

Optional Checker for possibly-present data

Java 8 introduced the `Optional` class, a container that is either empty or contains a non-null value.

Using `Optional` is intended to help programmers remember to check whether data is present or not. However, `Optional` itself is prone to misuse. The article [Nothing is better than the `Optional` type](#) gives reasons to use regular nullable references rather than `Optional`. However, if you do use `Optional`, then the Optional Checker will help you avoid `Optional`'s pitfalls.

Stuart Marks gave 7 rules to avoid problems with `Optional`:

1. Never, ever, use `null` for an `Optional` variable or return value.
2. Never use `Optional.get()` unless you can prove that the `Optional` is present.
3. Prefer alternative APIs over `Optional.isPresent()` and `Optional.get()`.
4. It's generally a bad idea to create an `Optional` for the specific purpose of chaining methods from it to get a value.
5. If an `Optional` chain has a nested `Optional` chain, or has an intermediate result of `Optional`, it's probably too complex.
6. Avoid using `Optional` in fields, method parameters, and collections.
7. Don't use an `Optional` to wrap any collection type (`List`, `Set`, `Map`). Instead, use an empty collection to represent the absence of values.

Rule #1 is guaranteed by the Nullness Checker (Chapter 3, page 27). Rules #2–#7 are guaranteed by the Optional Checker, described in this chapter. (Exception: Rule #5 is not yet implemented and will be checked by the Optional Checker in the future.)

Use of the Optional Checker guarantees that your program will not suffer a `NullPointerException` nor a `NoSuchElementException` when calling methods on an expression of `Optional` type.

5.1 How to run the Optional Checker

```
javac -processor optional MyFile.java ...
```

5.2 Optional annotations

These qualifiers make up the `Optional` type system:

@MaybePresent The annotated `Optional` container may or may not contain a value. This is the default type.

@Present The annotated `Optional` container definitely contains a (non-null) value.

@PolyPresent indicates qualifier polymorphism (see Section 26.2).

The subtyping hierarchy of the Optional Checker's qualifiers is shown in Figure 5.1.

Figure 5.1: The subtyping relationship of the Optional Checker’s qualifiers.

5.3 What the Optional Checker guarantees

The Optional Checker guarantees that your code will not throw an exception due to use of an absent `Optional` where a present `Optional` is needed. More specifically, the Optional Checker will issue a warning if you call `get` or `orElseThrow` on a `@MaybePresent` `Optional` receiver, because each of these methods throws an exception if the receiver is an absent `Optional`.

The Optional Checker does not check nullness properties, such as requiring that the argument to `of` is non-null or guaranteeing that the result of `get` is non-null. To obtain such a guarantee, run both the Optional Checker and the Nullness Checker (Chapter 3, page 27).

As with any checker, the guarantee is subject to certain limitations (see Section 2.3).

Chapter 6

Interning Checker

If the Interning Checker issues no errors for a given program, then all reference equality tests (i.e., all uses of “==”) are proper; that is, == is not misused where equals () should have been used instead.

Interning is a design pattern in which the same object is used whenever two different objects would be considered equal. Interning is also known as canonicalization or hash-consing, and it is related to the flyweight design pattern. Interning has two benefits: it can save memory, and it can speed up testing for equality by permitting use of ==.

The Interning Checker prevents two types of problems in your code. First, it prevents using == on non-interned values, which can result in subtle bugs. For example:

```
Integer x = new Integer(22);
Integer y = new Integer(22);
System.out.println(x == y); // prints false!
```

Second, the Interning Checker helps to prevent performance problems that result from failure to use interning. (See Section 2.3 for caveats to the checker’s guarantees.)

Interning is such an important design pattern that Java builds it in for these types: String, Boolean, Byte, Character, Integer, Short. Every string literal in the program is guaranteed to be interned (JLS §3.10.5), and the String.intern() method performs interning for strings that are computed at run time. The valueOf methods in wrapper classes always (Boolean, Byte) or sometimes (Character, Integer, Short) return an interned result (JLS §5.1.7). Users can also write their own interning methods for other types.

It is a proper optimization to use ==, rather than equals (), whenever the comparison is guaranteed to produce the same result — that is, whenever the comparison is never provided with two different objects for which equals () would return true. Here are three reasons that this property could hold:

1. Interning. A factory method ensures that, globally, no two different interned objects are equals () to one another. (For some classes, every instance is interned; however, in other cases it is possible for two objects of the class to be equals () to one another, even if one of them is interned.) Interned objects should always be immutable.
2. Global control flow. The program’s control flow is such that the constructor for class C is called a limited number of times, and with specific values that ensure the results are not equals () to one another. Objects of class C can always be compared with ==. Such objects may be mutable or immutable.
3. Local control flow. Even though not all objects of the given type may be compared with ==, the specific objects that can reach a given comparison may be.
 - When searching for an element (say, in a collection), == may be appropriate.
 - Some routines return either their argument, or a modified version of it. Your code might compare s == s.toLowerCase () to see whether a string contained any upper-case characters.

To eliminate Interning Checker errors, you will need to annotate the declarations of any expression used as an argument to ==. Thus, the Interning Checker could also have been called the Reference Equality Checker.

To run the Interning Checker, supply the -processor org.checkerframework.checker.interning.InterningChecker command-line option to javac. For examples, see Section 6.5.

Figure 6.1: Type hierarchy for the Interning type system.

6.1 Interning annotations

6.1.1 Interning qualifiers

These qualifiers are part of the Interning type system:

@Interned indicates a type that includes only interned values (no non-interned values).

@InternedDistinct indicates a type such that each value is not `equals()` to any other Java value. This is a stronger (more restrictive) property than `@Interned`, but is a weaker property than writing `@Interned` on a class declaration. For details, see Section 6.3.3.

@UnknownInterned indicates a type whose values might or might not be interned. It is used internally by the type system and is not written by programmers.

@PolyInterned indicates qualifier polymorphism (see Section 26.2).

6.1.2 Interning method and class annotations

@UsesObjectEquals is a class annotation (not a type annotation) that indicates that this class's `equals` method is the same as that of `Object`. In other words, neither this class nor any of its superclasses overrides the `equals` method. Since `Object.equals` uses reference equality, this means that for such a class, `==` and `equals` are equivalent, and so the Interning Checker does not issue errors or warnings for either one.

@InternMethod is a method declaration annotation that indicates that this method returns an interned object and may be invoked on an uninterned object. See Section 6.3.1 for more details.

6.2 Annotating your code with @Interned

In order to perform checking, you must annotate your code with the `@Interned` type annotation. A type annotated with `@Interned` contains the canonical representation of an object:

```
String s1 = ...; // type is (uninterned) "String"
@Interned String s2 = ...; // type is "@Interned String"
```

The Interning Checker ensures that only interned values can be assigned to `s2`.

6.3 Interned classes

An interned annotation on a class declaration indicates that all objects of a type are interned *except for newly created objects*. That means that all uses of such types are `@Interned` by default and the type `@UnknownInterned MyClass` is an invalid type.

An exception is *constructor results*. Constructor results and `this` within the body of the constructor are `@UnknownInterned` by default. Although `@UnknownInterned InternClass` is not a legal type, no “type.invalid” error is issued at constructor declarations. Instead, an “interned.object.creation” error is issued at the invocation of the constructor. The user should inspect this location and suppress the warning if the newly created object is interned.

For example:

```

@Interned class InternedClass {
    @UnknownInterned InternedClass() {
        // error, "this" is @UnknownInterned.
        @Interned InternedClass that = this;
    }

    @SuppressWarnings("intern") // Only creation of an InternedClass object.
    static final InternedClass ONE = new InternedClass();
}

```

6.3.1 The intern() methods

Some interned classes use an `intern()` method to look up the interned version of the object. These methods must be annotated with the declaration annotation `@InternMethod`. This allows the checker to verify that a newly created object is immediately interned and therefore not issue an interned object creation error.

```
new InternedClass().intern() // no error
```

Because an `intern` method is expected to be called on uninterned objects, the type of `this` in `intern` is implicitly `@UnknownInterned`. This will cause an error if `this` is used someplace where an interned object is expected. Some of these warnings will be false positives that should be suppressed by the user.

```

@InternMethod
public InternedClass intern() {
    // Type of "this" inside an @InternMethod is @UnknownInterned
    @Interned InternedClass that = this; // error

    if (!pool.contains(this)) {
        @SuppressWarnings("interning:assignment.type.incompatible")
        @Interned InternedClass internedThis = this;
        pool.add(internedThis);
    }
    return pool.get(this);
}

```

Some interned classes do not use an `intern` method to ensure that every object of that class is interned. For these classes, the user will have to manually inspect every constructor invocation and suppress the “interned.object.creation” error.

If every invocation of a constructor is guaranteed to be interned, then the user should annotate the constructor result with `@Interned` and suppress a warning at the constructor.

```

@Interned class AnotherInternedClass {
    // manually verified that all constructor invocations used such that all
    // new objects are interned
    @SuppressWarnings("super.invocation.invalid")
    @Interned AnotherInternedClass() {}
}

```

6.3.2 Default qualifiers and qualifiers for literals

The Interning Checker adds qualifiers to unannotated types, reducing the number of annotations that must appear in your code (see Section 27.4).

For a complete description of all defaulting rules for interning qualifiers, see the Javadoc for `InterningAnnotatedTypeFactory`.

6.3.3 InternedDistinct: values not equals() to any other value

The `@InternedDistinct` annotation represents values that are not `equals()` to any other value. Suppose expression `e` has type `@InternedDistinct`. Then `e.equals(x) == (e == x)`. Therefore, it is legal to use `==` whenever at least one of the operands has type `@InternedDistinct`.

`@InternedDistinct` is stronger (more restrictive) than `@Interned`. For example, consider these variables:

```
@Interned String i = "22";
String s = new Integer(22).toString();
```

The variable `i` is not `@InternedDistinct` because `i.equals(s)` is true.

`@InternedDistinct` is not as restrictive as stating that all objects of a given Java type are interned.

The `@InternedDistinct` annotation is rarely used, because it arises from coding paradigms that are tricky to reason about. One use is on static fields that hold canonical values of a type. Given this declaration:

```
class MyType {
    final static @InternedDistinct MyType SPECIAL = new MyType(...);
    ...
}
```

it would be legal to write `myValue == MyType.SPECIAL` rather than `myValue.equals(MyType.SPECIAL)`.

The `@InternedDistinct` is trusted (not verified), because it would be too complex to analyze the `equals()` method to ensure that no other value is `equals()` to a `@InternedDistinct` value. You will need to manually verify that it is only written in locations where its contract is satisfied. For example, here is one set of guidelines that you could check manually:

- The constructor is private.
- The factory method (whose return type is annotated with `@InternedDistinct` returns the canonical version for certain values.
- The class is final, so that subclasses cannot violate these properties.

6.4 What the Interning Checker checks

Objects of an `@Interned` type may be safely compared using the “`==`” operator.

The checker issues an error in two cases:

1. When a reference (in)equality operator (“`==`” or “`!=`”) has an operand of non-`@Interned` type. As a special case, the operation is permitted if either argument is of `@InternedDistinct` type
2. When a non-`@Interned` type is used where an `@Interned` type is expected.

This example shows both sorts of problems:

```
        Date date;
        @Interned Date idate;
@InternedDistinct Date ddate;
...
if (date == idate) ... // error: reference equality test is unsafe
idate = date;          // error: idate's referent might no longer be interned
ddate = idate;         // error: idate's referent might be equals() to some other value
```

The checker also issues a warning when `.equals` is used where `==` could be safely used. You can disable this behavior via the `javac -Alint=-dotequals` command-line option.

For a complete description of all checks performed by the checker, see the Javadoc for `InterningVisitor`.

You can also restrict which types the checker should examine and type-check, using the `-Acheckclass` option. For example, to find only the interning errors related to uses of `String`, you can pass `-Acheckclass=java.lang.String`. The Interning Checker always checks all subclasses and superclasses of the given class.

`com.sun.istack.internal.Interned` ⇒ `org.checkerframework.checker.interning.qual.Interned`

Figure 6.2: Correspondence between other interning annotations and the Checker Framework’s annotations.

6.4.1 Imprecision (false positive warnings) of the Interning Checker

The Interning Checker conservatively assumes that the `Character`, `Integer`, and `Short` `valueOf` methods return a non-interned value. In fact, these methods sometimes return an interned value and sometimes a non-interned value, depending on the run-time argument (JLS §5.1.7). If you know that the run-time argument to `valueOf` implies that the result is interned, then you will need to suppress an error. (The Interning Checker should make use of the Value Checker to estimate the upper and lower bounds on `char`, `int`, and `short` values so that it can more precisely determine whether the result of a given `valueOf` call is interned.)

6.5 Examples

To try the Interning Checker on a source file that uses the `@Interned` qualifier, use the following command:

```
javac -processor org.checkerframework.checker.interning.InterningChecker docs/examples/InterningExample.java
```

Compilation will complete without errors or warnings.

To see the checker warn about incorrect usage of annotations, use the following command:

```
javac -processor org.checkerframework.checker.interning.InterningChecker docs/examples/InterningExampleWithWarnings.java
```

The compiler will issue an error regarding violation of the semantics of `@Interned`.

The Daikon invariant detector (<http://plse.cs.washington.edu/daikon/>) is also annotated with `@Interned`. From directory `java/`, run `make check-interning`.

6.6 Other interning annotations

The Checker Framework’s interning annotations are similar to annotations used elsewhere.

If your code is already annotated with a different interning annotation, the Checker Framework can type-check your code. It treats annotations from other tools as if you had written the corresponding annotation from the Interning Checker, as described in Figure 6.2. If the other annotation is a declaration annotation, it may be moved; see Section 29.1.1.

Chapter 7

Lock Checker

The Lock Checker prevents certain concurrency errors by enforcing a locking discipline. A locking discipline indicates which locks must be held when a given operation occurs. You express the locking discipline by declaring a variable's type to have the qualifier `@GuardedBy("lockexpr")`. This indicates that the variable's value may be dereferenced only if the given lock is held.

To run the Lock Checker, supply the `-processor org.checkerframework.checker.lock.LockChecker` command-line option to `javac`. The `-AconcurrentSemantics` command-line option is always enabled for the Lock Checker (see Section 34.4.5).

7.1 What the Lock Checker guarantees

The Lock Checker gives the following guarantee. Suppose that expression e has type `@GuardedBy({"x", "y.z"})`. Then the value computed for e is only dereferenced by a thread when the thread holds locks x and $y.z$. Dereferencing a value is reading or writing one of its fields. The guarantee about e 's value holds not only if the expression e is dereferenced directly, but also if the value was first copied into a variable, returned as the result of a method call, etc. Copying a reference is always permitted by the Lock Checker, regardless of which locks are held.

A lock is held if it has been acquired but not yet released. Java has two types of locks. A monitor lock is acquired upon entry to a `synchronized` method or block, and is released on exit from that method or block. An explicit lock is acquired by a method call such as `Lock.lock()`, and is released by another method call such as `Lock.unlock()`. The Lock Checker enforces that any expression whose type implements `Lock` is used as an explicit lock, and all other expressions are used as monitor locks.

Ensuring that your program obeys its locking discipline is an easy and effective way to eliminate a common and important class of errors. If the Lock Checker issues no warnings, then your program obeys its locking discipline. However, your program might still have other types of concurrency errors. For example, you might have specified an inadequate locking discipline because you forgot some `@GuardedBy` annotations. Your program might release and re-acquire the lock, when correctness requires it to hold it throughout a computation. And, there are other concurrency errors that cannot, or should not, be solved with locks.

7.2 Lock annotations

This section describes the lock annotations you can write on types and methods.

7.2.1 Type qualifiers

`@GuardedBy(exprSet)` If a variable x has type `@GuardedBy("expr")`, then a thread may dereference the value referred to by x only when the thread holds the lock that $expr$ currently evaluates to.

Figure 7.1: The subtyping relationship of the Lock Checker’s qualifiers. `@GuardedBy({})` is the default type qualifier for unannotated types (except all CLIMB-to-top locations other than upper bounds and exception parameters — see Section 27.5.3).

The `@GuardedBy` annotation can list multiple expressions, as in `@GuardedBy({"expr1", "expr2"})`, in which case the dereference is permitted only if the thread holds all the locks.

Section 27.8 explains which expressions the Lock Checker is able to analyze as lock expressions. These include `<self>`, i.e. the value of the annotated reference (non-primitive) variable. For example, `@GuardedBy("<self>") Object o` indicates that the value referenced by `o` is guarded by the intrinsic (monitor) lock of the value referenced by `o`.

`@GuardedBy({})`, which means the value is always allowed to be dereferenced, is the default type qualifier that is used for all locations where the programmer does not write an explicit locking type qualifier (except all CLIMB-to-top locations other than upper bounds and exception parameters — see Section 27.5.3). (Section 7.5.4 discusses this choice.) It is also the conservative default type qualifier for method parameters in unannotated libraries (see Chapter 31, page 184).

@GuardedByUnknown If a variable `x` has type `@GuardedByUnknown`, then it is not known which locks protect `x`’s value. Those locks might even be out of scope (inaccessible) and therefore unable to be written in the annotation. The practical consequence is that the value referred to by `x` can never be dereferenced.

Any value can be assigned to a variable of type `@GuardedByUnknown`. In particular, if it is written on a formal parameter, then any value, including one whose locks are not currently held, may be passed as an argument.

`@GuardedByUnknown` is the conservative default type qualifier for method receivers in unannotated libraries (see Chapter 31, page 184).

@GuardedByBottom If a variable `x` has type `@GuardedByBottom`, then the value referred to by `x` is null and can never be dereferenced.

Figure 7.1 shows the type hierarchy of these qualifiers. All `@GuardedBy` annotations are incomparable: if `exprSet1` \neq `exprSet2`, then `@GuardedBy(exprSet1)` and `@GuardedBy(exprSet2)` are siblings in the type hierarchy. You might expect that `@GuardedBy({"x", "y"}) T` is a subtype of `@GuardedBy({"x"}) T`. The first type requires two locks to be held, and the second requires only one lock to be held and so could be used in any situation where both locks are held. The type system conservatively prohibits this in order to prevent type-checking loopholes that would result from aliasing and side effects — that is, from having two mutable references, of different types, to the same data. See Section 7.4.2 for an example of a problem that would occur if this rule were relaxed.

Polymorphic type qualifiers

@GuardSatisfied(index) If a variable `x` has type `@GuardSatisfied`, then all lock expressions for `x`’s value are held.

As with other qualifier-polymorphism annotations (Section 26.2), the `index` argument indicates when two values are guarded by the same (unknown) set of locks.

`@GuardSatisfied` is only allowed in method signatures: on formal parameters (including the receiver) and return types. It may not be written on fields. Also, it is a limitation of the current design that `@GuardSatisfied` may not be written on array elements or on local variables.

A return type can only be annotated with `@GuardSatisfied(index)`, not `@GuardSatisfied`.

See Section 7.4.6 for an example of a use of `@GuardSatisfied`.

7.2.2 Declaration annotations

The Lock Checker supports several annotations that specify method behavior. These are declaration annotations, not type annotations: they apply to the method itself rather than to some particular type.

Method pre-conditions and post-conditions

@Holding(String[] locks) All the given lock expressions are held at the method call site.

@EnsuresLockHeld(String[] locks) The given lock expressions are locked upon method return if the method terminates successfully. This is useful for annotating a method that acquires a lock such as `ReentrantLock.lock()`.

@EnsuresLockHeldIf(String[] locks, boolean result) If the annotated method returns the given boolean value (true or false), the given lock expressions are locked upon method return if the method terminates successfully. This is useful for annotating a method that conditionally acquires a lock. See Section 7.4.4 for examples.

Side effect specifications

@LockingFree The method does not acquire or release locks, directly or indirectly. The method is not synchronized, it contains no synchronized blocks, it contains no calls to lock or unlock methods, and it contains no calls to methods that are not themselves `@LockingFree`.

Since `@SideEffectFree` implies `@LockingFree`, if both are applicable then you only need to write `@SideEffectFree`.

@ReleasesNoLocks The method maintains a strictly nondecreasing lock hold count on the current thread for any locks that were held prior to the method call. The method might acquire locks but then release them, or might acquire locks but not release them (in which case it should also be annotated with `@EnsuresLockHeld` or `@EnsuresLockHeldIf`).

This is the default for methods being type-checked that have no `@LockingFree`, `@MayReleaseLocks`, `@SideEffectFree`, or `@Pure` annotation.

@MayReleaseLocks The method may release locks that were held prior to the method being called. You can write this when you are certain the method releases locks, or when you don't know whether the method releases locks. This is the conservative default for methods in unannotated libraries (see Chapter 31, page 184).

7.3 Type-checking rules

In addition to the standard subtyping rules enforcing the subtyping relationship described in Figure 7.1, the Lock Checker enforces the following additional rules.

7.3.1 Polymorphic qualifiers

@GuardSatisfied The overall rules for polymorphic qualifiers are given in Section 26.2.

Here are additional constraints for (pseudo-)assignments:

- If the left-hand side has type `@GuardSatisfied` (with or without an index), then all locks mentioned in the right-hand side's `@GuardedBy` type must be currently held.
- A formal parameter with type qualifier `@GuardSatisfied` without an index cannot be assigned to.
- If the left-hand side is a formal parameter with type `@GuardSatisfied(index)`, the right-hand-side must have identical `@GuardSatisfied(index)` type.

If a formal parameter type is annotated with `@GuardSatisfied` without an index, then that formal parameter type is unrelated to every other type in the `@GuardedBy` hierarchy, including other occurrences of `@GuardSatisfied` without an index.

`@GuardSatisfied` may not be used on formal parameters, receivers, or return types of a method annotated with `@MayReleaseLocks`.

7.3.2 Dereferences

@GuardedBy An expression of type `@GuardedBy(eset)` may be dereferenced only if all locks in *eset* are held.

@GuardSatisfied An expression of type `@GuardSatisfied` may be dereferenced.

Not @GuardedBy or @GuardSatisfied An expression whose type is not annotated with `@GuardedBy` or `@GuardSatisfied` may not be dereferenced.

7.3.3 Primitive types, boxed primitive types, and Strings

Primitive types, boxed primitive types (such as `java.lang.Integer`), and type `java.lang.String` are annotated with `@GuardedBy({})`. It is an error for the programmer to annotate any of these types with an annotation from the `@GuardedBy` type hierarchy, including `@GuardedBy({})`.

7.3.4 Overriding

Overriding methods annotated with @Holding If class *B* overrides method *m* from class *A*, then the expressions in *B*'s `@Holding` annotation must be a subset of or equal to that of *A*'s `@Holding` annotation.

Overriding methods annotated with side effect annotations If class *B* overrides method *m* from class *A*, then the side effect annotation on *B*'s declaration of *m* must be at least as strong as that in *A*'s declaration of *m*. From weakest to strongest, the side effect annotations processed by the Lock Checker are:

```
@MayReleaseLocks
@ReleasesNoLocks
@LockingFree
@SideEffectFree
@Pure
```

7.3.5 Side effects

Releasing explicit locks Any method that releases an explicit lock must be annotated with `@MayReleaseLocks`. The Lock Checker issues a warning if it encounters a method declaration annotated with `@MayReleaseLocks` and having a formal parameter or receiver annotated with `@GuardSatisfied`. This is because the Lock Checker cannot guarantee that the guard will be satisfied throughout the body of a method if that method may release a lock.

No side effects on lock expressions If expression *expr* is used to acquire a lock, then *expr* must evaluate to the same value, starting from when *expr* is used to acquire a lock until *expr* is used to release the lock. An expression is used to acquire a lock if it is the receiver at a call site of a synchronized method, is the expression in a synchronized block, or is the argument to a lock method.

Locks are released after possible side effects After a call to a method annotated with `@LockingFree`, `@ReleasesNoLocks`, `@SideEffectFree`, or `@Pure`, the Lock Checker's estimate of held locks after a method call is the same as that prior to the method call. After a call to a method annotated with `@MayReleaseLocks`, the estimate of held locks is conservatively reset to the empty set, except for those locks specified to be held after the call by an `@EnsuresLockHeld` or `@EnsuresLockHeldIf` annotation on the method. Assignments to variables also cause the estimate of held locks to be conservatively reduced to a smaller set if the Checker Framework determines that the assignment might have side-effected a lock expression. For more information on side effects, please refer to Section 27.7.5.

7.4 Examples

The Lock Checker guarantees that a value that was computed from an expression of `@GuardedBy` type is dereferenced only when the current thread holds all the expressions in the `@GuardedBy` annotation.

7.4.1 Examples of @GuardedBy

The following example demonstrates the basic type-checking rules.

```
class MyClass {
    final ReentrantLock lock; // Initialized in the constructor

    @GuardedBy("lock") Object x = new Object();
    @GuardedBy("lock") Object y = x; // OK, since dereferences of y will require "lock" to be held.
    @GuardedBy({}) Object z = x; // ILLEGAL since dereferences of z don't require "lock" to be held.
    @GuardedBy("lock") Object myMethod() { // myMethod is implicitly annotated with @ReleasesNoLocks.
        return x; // OK because the return type is annotated with @GuardedBy("lock")
    }

    [...]

    void exampleMethod() {
        x.toString(); // ILLEGAL because the lock is not known to be held
        y.toString(); // ILLEGAL because the lock is not known to be held
        myMethod().toString(); // ILLEGAL because the lock is not known to be held
        lock.lock();
        x.toString(); // OK: the lock is known to be held
        y.toString(); // OK: the lock is known to be held, and toString() is annotated with @SideEffectFree.
        myMethod().toString(); // OK: the lock is known to be held, since myMethod
                               // is implicitly annotated with @ReleasesNoLocks.
    }
}
```

Note that the expression `new Object()` is inferred to have type `@GuardedBy("lock")` because it is immediately assigned to a newly-declared variable having type annotation `@GuardedBy("lock")`. You could explicitly write `new @GuardedBy("lock") Object()` but it is not required.

The following example demonstrates that using `<self>` as a lock expression allows a guarded value to be dereferenced even when the original variable name the value was originally assigned to falls out of scope.

```
class MyClass {
    private final @GuardedBy("<self>") Object x = new Object();
    void method() {
        x.toString(); // ILLEGAL because x is not known to be held.
        synchronized(x) {
            x.toString(); // OK: x is known to be held.
        }
    }
}

public @GuardedBy("<self>") Object get_x() {
    return x; // OK, since the return type is @GuardedBy("<self>").
}

class MyOtherClass {
    void method() {
        MyClass m = new MyClass();
        final @GuardedBy("<self>") Object o = m.get_x();
        o.toString(); // ILLEGAL because o is not known to be held.
    }
}
```

```

    synchronized(o) {
        o.toString(); // OK: o is known to be held.
    }
}
}

```

7.4.2 @GuardedBy({"a", "b"}) is not a subtype of @GuardedBy({"a"})

@GuardedBy(exprSet)

The following example demonstrates the reason the Lock Checker enforces the following rule: if $exprSet1 \neq exprSet2$, then `@GuardedBy(exprSet1)` and `@GuardedBy(exprSet2)` are siblings in the type hierarchy.

```

class MyClass {
    final Object lockA = new Object();
    final Object lockB = new Object();
    @GuardedBy("lockA") Object x = new Object();
    @GuardedBy({"lockA", "lockB"}) Object y = new Object();
    void myMethod() {
        y = x; // ILLEGAL; if legal, later statement x.toString() would cause trouble
        synchronized(lockA) {
            x.toString(); // dereferences y's value without holding lock lockB
        }
    }
}

```

If the Lock Checker permitted the assignment $y = x$, then the undesired dereference would be possible.

7.4.3 Examples of @Holding

The following example shows the interaction between `@GuardedBy` and `@Holding`:

```

void helper1(@GuardedBy("myLock") Object a) {
    a.toString(); // ILLEGAL: the lock is not held
    synchronized(myLock) {
        a.toString(); // OK: the lock is held
    }
}
@Holding("myLock")
void helper2(@GuardedBy("myLock") Object b) {
    b.toString(); // OK: the lock is held
}
void helper3(@GuardedBy("myLock") Object d) {
    d.toString(); // ILLEGAL: the lock is not held
}
void myMethod2(@GuardedBy("myLock") Object e) {
    helper1(e); // OK to pass to another routine without holding the lock
               // (but helper1's body has an error)
    e.toString(); // ILLEGAL: the lock is not held
    synchronized (myLock) {
        helper2(e); // OK: the lock is held
        helper3(e); // OK, but helper3's body has an error
    }
}

```

7.4.4 Examples of @EnsuresLockHeld and @EnsuresLockHeldIf

@EnsuresLockHeld and @EnsuresLockHeldIf are primarily intended for annotating JDK locking methods, as in:

```
package java.util.concurrent.locks;

class ReentrantLock {

    @EnsuresLockHeld("this")
    public void lock();

    @EnsuresLockHeldIf (expression="this", result=true)
    public boolean tryLock();

    ...
}
```

They can also be used to annotate user methods, particularly for higher-level lock constructs such as a Monitor, as in this simplified example:

```
public class Monitor {

    private final ReentrantLock lock; // Initialized in the constructor

    ...

    @EnsuresLockHeld("lock")
    public void enter() {
        lock.lock();
    }

    ...
}
```

7.4.5 Example of @LockingFree, @ReleasesNoLocks, and @MayReleaseLocks

@LockingFree is useful when a method does not make any use of synchronization or locks but causes other side effects (hence @SideEffectFree is not appropriate). @SideEffectFree implies @LockingFree, therefore if both are applicable, you should only write @SideEffectFree. @ReleasesNoLocks has a weaker guarantee than @LockingFree, and @MayReleaseLocks provides no guarantees.

```
private Object myField;
private final ReentrantLock lock; // Initialized in the constructor
private @GuardedBy("lock") Object x; // Initialized in the constructor

[...]

// This method does not use locks or synchronization, but it cannot
// be annotated as @SideEffectFree since it alters myField.
@LockingFree
void myMethod() {
    myField = new Object();
}
```

```

@SideEffectFree
int mySideEffectFreeMethod() {
    return 0;
}

@MayReleaseLocks
void myUnlockingMethod() {
    lock.unlock();
}

@ReleasesNoLocks
void myLockingMethod() {
    lock.lock();
}

@MayReleaseLocks
void clientMethod() {
    if (lock.tryLock()) {
        x.toString(); // OK: the lock is held
        myMethod();
        x.toString(); // OK: the lock is still held since myMethod is locking-free
        mySideEffectFreeMethod();
        x.toString(); // OK: the lock is still held since mySideEffectFreeMethod is side-effect-free
        myUnlockingMethod();
        x.toString(); // ILLEGAL: myUnlockingMethod may have released a lock
    }
    if (lock.tryLock()) {
        x.toString(); // OK: the lock is held
        myLockingMethod();
        x.toString(); // OK: the lock is held
    }
    if (lock.isHeldByCurrentThread()) {
        x.toString(); // OK: the lock is known to be held
    }
}

```

7.4.6 Polymorphism and method formal parameters with unknown guards

The polymorphic `@GuardSatisfied` type annotation allows a method body to dereference the method's formal parameters even if the `@GuardedBy` annotations on the actual parameters are unknown at the method declaration site.

The declaration of `StringBuffer.append(String str)` is annotated as:

```

@LockingFree
public @GuardSatisfied(1) StringBuffer append(@GuardSatisfied(1) StringBuffer this,
                                             @GuardSatisfied(2) String str)

```

The method manipulates the values of its arguments, so all their locks must be held. However, the declaration does not know what those are and they might not even be in scope at the declaration. Therefore, the declaration cannot use `@GuardedBy` and must use `@GuardSatisfied`. The arguments to `@GuardSatisfied` indicate that the receiver and result (which are the same value) are guarded by the same (unknown, possibly empty) set of locks, and the `str` parameter may be guarded by a different set of locks.

The `@LockingFree` annotation indicates that this method makes no use of locks or synchronization. Given these annotations on `append`, the following code type-checks:

```
final ReentrantLock lock1, lock2; // Initialized in the constructor
@GuardedBy("lock1") StringBuffer filename;
@GuardedBy("lock2") StringBuffer extension;
...
lock1.lock();
lock2.lock();
filename = filename.append(extension);
```

7.5 More locking details

This section gives some details that are helpful for understanding how Java locking and the Lock Checker works.

7.5.1 Two types of locking: monitor locks and explicit locks

Java provides two types of locking: monitor locks and explicit locks.

- A `synchronized(E)` block acquires the lock on the value of *E*; similarly, a method declared using the `synchronized` method modifier acquires the lock on the method receiver when called. (More precisely, the current thread locks the monitor associated with the value of *E*; see JLS §17.1.) The lock is automatically released when execution exits the block or the method body, respectively. We use the term “monitor lock” for a lock acquired using a `synchronized` block or `synchronized` method modifier.
- A method call, such as `Lock.lock()`, acquires a lock that implements the `Lock` interface. The lock is released by another method call, such as `Lock.unlock()`. We use the term “explicit lock” for a lock expression acquired in this way.

You should not mix the two varieties of locking, and the Lock Checker enforces this. To prevent an object from being used both as a monitor and an explicit lock, the Lock Checker issues a warning if a `synchronized(E)` block’s expression *E* has a type that implements `Lock`.

7.5.2 Held locks and held expressions; aliasing

Whereas Java locking is defined in terms of values, Java programs are written in terms of expressions. We say that a lock expression is held if the value to which the expression currently evaluates is held.

The Lock Checker conservatively estimates the expressions that are held at each point in a program. The Lock Checker does not track aliasing (different expressions that evaluate to the same value); it only considers the exact expression used to acquire a lock to be held. After any statement that might side-effect a held expression or a lock expression, the Lock Checker conservatively considers the expression to be no longer held.

Section 27.8 explains which Java expressions the Lock Checker is able to analyze as lock expressions.

The `@LockHeld` and `@LockPossiblyHeld` type qualifiers are used internally by the Lock Checker and should never be written by the programmer. If you see a warning mentioning `@LockHeld` or `@LockPossiblyHeld`, please contact the Checker Framework developers as it is likely to indicate a bug in the Checker Framework.

7.5.3 Run-time checks for locking

When you perform a run-time check for locking, such as `if (explicitLock.isHeldByCurrentThread()) {...}` or `if (Thread.holdsLock(monitorLock)) {...}`, then the Lock Checker considers the lock expression to be held within the scope of the test. For more details, see Section 27.7.

7.5.4 Discussion of default qualifier

The default qualifier for unannotated types is `@GuardedBy({})`. This default forces you to write explicit `@GuardSatisfied` in method signatures in the common case that clients ensure that all locks are held.

It might seem that `@GuardSatisfied` would be a better default for method signatures, but such a default would require even more annotations. The reason is that `@GuardSatisfied` cannot be used on fields. If `@GuardedBy({})` is the default for fields but `@GuardSatisfied` is the default for parameters and return types, then getters, setters, and many other types of methods do not type-check without explicit lock qualifiers.

7.5.5 Discussion of `@Holding`

A programmer might choose to use the `@Holding` method annotation in two different ways: to specify correctness constraints for a synchronization protocol, or to summarize intended usage. Both of these approaches are useful, and the Lock Checker supports both.

Synchronization protocol `@Holding` can specify a synchronization protocol that is not expressible as locks over the parameters to a method. For example, a global lock or a lock on a different object might need to be held. By requiring locks to be held, you can create protocol primitives without giving up the benefits of the annotations and checking of them.

Method summary that simplifies reasoning `@Holding` can be a method summary that simplifies reasoning. In this case, the `@Holding` doesn't necessarily introduce a new correctness constraint; the program might be correct even if the lock were not already acquired.

Rather, here `@Holding` expresses a fact about execution: when execution reaches this point, the following locks are known to be already held. This fact enables people and tools to reason intra- rather than inter-procedurally.

In Java, it is always legal to re-acquire a lock that is already held, and the re-acquisition always works. Thus, whenever you write

```
@Holding("myLock")
void myMethod() {
    ...
}
```

it would be equivalent, from the point of view of which locks are held during the body, to write

```
void myMethod() {
    synchronized (myLock) { // no-op: re-acquire a lock that is already held
        ...
    }
}
```

It is better to write a `@Holding` annotation rather than writing the extra synchronized block. Here are reasons:

- The annotation documents the fact that the lock is intended to already be held; that is, the method's contract requires that the lock be held when the method is called.
- The Lock Checker enforces that the lock is held when the method is called, rather than masking a programmer error by silently re-acquiring the lock.
- The version with a synchronized statement can deadlock if, due to a programmer error, the lock is not already held. The Lock Checker prevents this type of error.
- The annotation has no run-time overhead. The lock re-acquisition consumes time, even if it succeeds.

net.jcip.annotations.GuardedBy	⇒	org.checkerframework.checker.lock.qual.GuardedBy (for fields), or
javax.annotation.concurrent.GuardedBy		org.checkerframework.checker.lock.qual.Holding (for methods)

Figure 7.2: Correspondence between other lock annotations and the Checker Framework’s annotations.

7.6 Other lock annotations

The Checker Framework’s lock annotations are similar to annotations used elsewhere.

If your code is already annotated with a different lock annotation, the Checker Framework can type-check your code. It treats annotations from other tools as if you had written the corresponding annotation from the Lock Checker, as described in Figure 7.2. If the other annotation is a declaration annotation, it may be moved; see Section 29.1.1.

7.6.1 Relationship to annotations in *Java Concurrency in Practice*

The book *Java Concurrency in Practice* [GPB⁺06] defines a `@GuardedBy` annotation that is the inspiration for ours. The book’s `@GuardedBy` serves two related but distinct purposes:

- When applied to a field, it means that the given lock must be held when accessing the field. The lock acquisition and the field access may occur arbitrarily far in the future.
- When applied to a method, it means that the given lock must be held by the caller at the time that the method is called — in other words, at the time that execution passes the `@GuardedBy` annotation.

The Lock Checker renames the method annotation to `@Holding`, and it generalizes the `@GuardedBy` annotation into a type annotation that can apply not just to a field but to an arbitrary type (including the type of a parameter, return value, local variable, generic type parameter, etc.). Another important distinction is that the Lock Checker’s annotations express and enforce a locking discipline over values, just like the JLS expresses Java’s locking semantics; by contrast, JCIP’s annotations express a locking discipline that protects variable names and does not prevent race conditions. This makes the annotations more expressive and also more amenable to automated checking. It also accommodates the distinct meanings of the two annotations, and resolves ambiguity when `@GuardedBy` is written in a location that might apply to either the method or the return type.

(The JCIP book gives some rationales for reusing the annotation name for two purposes. One rationale is that there are fewer annotations to learn. Another rationale is that both variables and methods are “members” that can be “accessed” and `@GuardedBy` creates preconditions for doing so. Variables can be accessed by reading or writing them (putfield, getfield), and methods can be accessed by calling them (invokevirtual, invokeinterface). This informal intuition is inappropriate for a tool that requires precise semantics.)

7.7 Possible extensions

The Lock Checker validates some uses of locks, but not all. It would be possible to enrich it with additional annotations. This would increase the programmer annotation burden, but would provide additional guarantees.

Lock ordering: Specify that one lock must be acquired before or after another, or specify a global ordering for all locks. This would prevent deadlock.

Not-holding: Specify that a method must not be called if any of the listed locks are held.

These features are supported by Clang’s thread-safety analysis.

Chapter 8

Index Checker for sequence bounds (arrays and strings)

The Index Checker warns about potentially out-of-bounds accesses to sequence data structures, such as arrays and strings.

The Index Checker prevents `IndexOutOfBoundsException`s that result from an index expression that might be negative or might be equal to or larger than the sequence's length. It also prevents `NegativeArraySizeExceptions` that result from a negative array dimension in an array creation expression. (A caveat: the Index Checker does not check for arithmetic overflow. If an expression overflows, the Index Checker might fail to warn about a possible exception. This is unlikely to be a problem in practice unless you have an array whose length is `Integer.MAX_VALUE`.)

The programmer can write annotations that indicate which expressions are indices for which sequences. The Index Checker prohibits any operation that may violate these properties, and the Index Checker takes advantage of these properties when verifying indexing operations. Typically, a programmer writes few annotations, because the Index Checker infers properties of indexes from the code around them. For example, it will infer that `x` is positive within the `then` block of an `if (x > 0)` statement. The programmer does need to write field types and method pre-conditions or post-conditions. For instance, if a method's formal parameter is used as an index for `myArray`, the programmer might need to write an `@IndexFor("myArray")` annotation on the formal parameter's types.

The Index Checker checks fixed-size data structures, whose size is never changed after creation. A fixed-size data structure has no `add` or `remove` operation. Examples are strings and arrays, and you can add support for other fixed-size data structures (see Section 8.9).

To run the Index Checker, run the command

```
javac -processor index MyJavaFile.java
```

Recall that in Java, type annotations are written before the type; in particular, array annotations appear immediately before `[]`. Here is how to declare a length-9 array of positive integers:

```
@Positive int @ArrayLen(9) []
```

Multi-dimensional arrays are similar. Here is how to declare a length-2 array of length-4 arrays:

```
String @ArrayLen(2) [] @ArrayLen(4) []
```

8.1 Index Checker structure and annotations

Internally, the Index Checker computes information about integers that might be indices:

- the lower bound on an integer, such as whether it is known to be positive (Section 8.2)

- the upper bound on an integer, such as whether it is less than the length of a given sequence (Section 8.3)
- whether an integer came from calling the JDK’s binary search routine on an array (Section 8.6)
- whether an integer came from calling a string search routine (Section 8.7)

and about sequence lengths:

- the minimum length of a sequence, such “myArray contains at least 3 elements” (Section 8.4)
- whether two sequences have the same length (Section 8.5)

The Index Checker checks of all these properties at once, but this manual discusses each type system in a different section. There are some annotations that are shorthand for writing multiple annotations, each from a different type system:

@IndexFor(String[] names) The value is a valid index for the named sequences. For example, the `String.charAt(int)` method is declared as

```
class String {
    char charAt(@IndexFor("this") index) { ... }
}
```

More generally, a variable declared as `@IndexFor("someArray") int i` has type `@IndexFor("someArray") int` and its run-time value is guaranteed to be non-negative and less than the length of `someArray`. You could also express this as `@NonNegative @LTLengthOf("someArray") int i`, but `@IndexFor("someArray") int i` is more concise.

@IndexOrHigh(String[] names) The value is non-negative and is less than or equal to the length of each named sequence. This type combines `@NonNegative` and `@LTEqLengthOf`.

For example, the `Arrays.fill` method is declared as

```
class Arrays {
    void fill(Object[] a, @IndexFor("#1") int fromIndex, @IndexOrHigh("#1") int toIndex, Object val)
}
```

@LengthOf(String[] names) The value is exactly equal to the length of the named sequences. In the implementation, this type aliases `@IndexOrHigh`, so writing it only adds documentation (although future versions of the Index Checker may use it to improve precision).

@IndexOrLow(String[] names) The value is -1 or is a valid index for each named sequence. This type combines `@GTENegativeOne` and `@LTLengthOf`.

@PolyIndex indicates qualifier polymorphism. This type combines `@PolyLowerBound` and `@PolyUpperBound`. For a description of qualifier polymorphism, see Section 26.2.

@PolyLength is a special polymorphic qualifier that combines `@PolySameLen` and `@PolyValue` from the Constant Value Checker (see Chapter 21, page 127). `@PolyLength` exists as a shorthand for these two annotations, since they often appear together.

8.2 Lower bounds

The Index Checker issues an error when a sequence is indexed by an integer that might be negative. The Lower Bound Checker uses a type system (Figure 8.1) with the following qualifiers:

@Positive The value is 1 or greater, so it is not too low to be used as an index. Note that this annotation is trusted by the Constant Value Checker, so if the Constant Value Checker is run on code containing this annotation, the Lower Bound Checker must be run on the same code in order to guarantee soundness.

@NonNegative The value is 0 or greater, so it is not too low to be used as an index.

@GTENegativeOne The value is -1 or greater. It may not be used as an index for a sequence, because it might be too low. (“GTE” stands for “Greater Than or Equal to”.)

@PolyLowerBound indicates qualifier polymorphism. For a description of qualifier polymorphism, see Section 26.2.

Figure 8.1: The two type hierarchies for integer types used by the Index Checker. On the left is a type system for lower bounds. On the right is a type system for upper bounds. Qualifiers written in gray should never be written in source code; they are used internally by the type system. "myArray" in the Upper Bound qualifiers is an example of an array's name.

@LowerBoundUnknown There is no information about the value. It may not be used as an index for a sequence, because it might be too low.

@LowerBoundBottom The value cannot take on any integral types. The bottom type, which should not need to be written by the programmer.

8.3 Upper bounds

The Index Checker issues an error when a sequence index might be too high. To do this, it maintains information about which expressions are safe indices for which sequences. The length of a sequence is `arr.length` for arrays and `str.length()` for strings. It uses a type system (Figure 8.1) with the following qualifiers:

It issues an error when a sequence `arr` is indexed by an integer that is not of type `@LTLengthOf("arr")` or `@LTOMLengthOf("arr")`.

@LTLengthOf(String[] names, String[] offset) An expression with this type has value less than the length of each sequence listed in `names`. The expression may be used as an index into any of those sequences, if it is non-negative. For example, an expression of type `@LTLengthOf("a") int` might be used as an index to `a`. The type `@LTLengthOf({"a", "b"})` is a subtype of both `@LTLengthOf("a")` and `@LTLengthOf("b")`. (“LT” stands for “Less Than”.)

`@LTLengthOf` takes an optional `offset` element, meaning that the annotated expression plus the `offset` is less than the length of the given sequence. For example, suppose expression `e` has type `@LTLengthOf(value = {"a", "b"}, offset = {"-1", "x"})`. Then `e - 1` is less than `a.length`, and `e + x` is less than `b.length`. This helps to make the checker more precise. Programmers rarely need to write the `offset` element.

@LTEqLengthOf(String[] names) An expression with this type has value less than or equal to the length of each sequence listed in `names`. It may not be used as an index for these sequences, because it might be too high. `@LTEqLengthOf({"a", "b"})` is a subtype of both `@LTEqLengthOf("a")` and `@LTEqLengthOf("b")`. (“LTEq” stands for “Less Than or Equal to”.)

@PolyUpperBound indicates qualifier polymorphism. For a description of qualifier polymorphism, see Section 26.2.

@LTOMLengthOf(String[] names) An expression with this type has value at least 2 less than the length of each sequence listed in `names`. It may always be used as an index for a sequence listed in `names`, if it is non-negative. This type exists to allow the checker to infer the safety of loops of the form:

```
for (int i = 0; i < array.length - 1; ++i) {
    arr[i] = arr[i+1];
}
```

This annotation should rarely (if ever) be written by the programmer; usually `@LTLengthOf(String[] names)` should be written instead. `@LTOMLengthOf({"a", "b"})` is a subtype of both `@LTOMLengthOf("a")` and `@LTOMLengthOf("b")`. (“LTOM” stands for “Less Than One Minus”, because another way of saying “at least 2 less than `a.length`” is “less than `a.length-1`”).

@UpperBoundUnknown There is no information about the upper bound on the value of an expression with this type. It may not be used as an index for a sequence, because it might be too high. This type is the top type, and should never need to be written by the programmer.

@UpperBoundBottom This is the bottom type for the upper bound type system. It should never need to be written by the programmer.

The following method annotations can be used to establish a method postcondition that ensures that a certain expression is a valid index for a sequence:

@EnsuresLTLengthOf(String[] value, String[] targetValue, String[] offset) When the method with this annotation returns, the expression (or all the expressions) given in the `value` element is less than the length of the given sequences with the given offsets. More precisely, the expression has the `@LTLengthOf` qualifier with the `value` and `offset` arguments taken from the `targetValue` and `offset` elements of this annotation.

@EnsuresLTLengthOfIf(String[] expression, boolean result, String[] targetValue, String[] offset) If the method with this annotation returns the given boolean value, then the given expression (or all the expressions) is less than the length of the given sequences with the given offsets.

There is one declaration annotation that indicates the relationship between two sequences:

@HasSubsequence(String[] value, String[] from, String[] to) indicates that a subsequence (from `from` to `to`) of the annotated sequence is equal to some other sequence, named by `value`.

For example, to indicate that `shorter` is a subsequence of `longer`:

```
int startIndex;
int endIndex;
int[] shorter;
@HasSubsequence(value="shorter", from="this.start", to="this.end")
int[] longer;
```

Thus, a valid index into `shorter` is also a valid index (between `start` and `end-1` inclusive) into `longer`. More generally, if `x` is `@IndexFor("shorter")` in the example above, then `start + x` is `@IndexFor("longer")`. If `y` is `@IndexFor("longer")` and `@LessThan("end")`, then `y - start` is `@IndexFor("shorter")`. Finally, `end - start` is `@IndexOrHigh("shorter")`.

This annotation is in part checked and in part trusted. When an array is assigned to `longer`, three facts are checked: that `start` is non-negative, that `start` is less than or equal to `end`, and that `end` is less than or equal to the length of `longer`. This ensures that the indices are valid. The programmer must manually verify that the value of `shorter` equals the subsequence that they describe.

8.4 Sequence minimum lengths

The Index Checker estimates, for each sequence expression, how long its value might be at run time by computing a minimum length that the sequence is guaranteed to have. This enables the Index Checker to verify indices that are compile-time constants. For example, this code:

```
String getThirdElement(String[] arr) {
    return arr[2];
}
```

is legal if `arr` has at least three elements, which can be indicated in this way:

```
String getThirdElement(String @MinLen(3) [] arr) {
    return arr[2];
}
```

When the index is not a compile-time constant, as in `arr[i]`, then the Index Checker depends not on a `@MinLen` annotation but on `i` being annotated as `@LTLengthOf("arr")`.

The `MinLen` type qualifier is implemented in practice by the Constant Value Checker, using `@ArrayLenRange` annotations (see Chapter 21, page 127). This means that errors related to the minimum lengths of arrays must be suppressed using the "value" argument to `@SuppressWarnings`. `@ArrayLenRange` and `@ArrayLen` annotations can also be used to establish the minimum length of a sequence, if a more precise estimate of length is known. For example, if `arr` is known to have exactly three elements:

```
String getThirdElement(String @ArrayLen(3) [] arr) {
    return arr[2];
}
```

The following type qualifiers (from the Chapter 21, page 127) can establish the minimum length of a sequence:

@MinLen(int value) The value of an expression of this type is a sequence with at least `value` elements. The default annotation is `@MinLen(0)`, and it may be applied to non-sequences. `@MinLen(x)` is a subtype of `@MinLen(x - 1)`. An `@MinLen` annotation is treated internally as an `@ArrayLenRange` with only its `from` field filled.

@ArrayLen(int[] value) The value of an expression of this type is a sequence whose length is exactly one of the integers listed in its argument. The argument can contain at most ten integers; larger collections of integers are converted to `@ArrayLenRange` annotations. The minimum length of a sequence with this annotation is the smallest element of the argument.

@ArrayLenRange(int from, int to) The value of an expression of this type is a sequence whose length is bounded by its arguments, inclusive. The minimum length of a sequence with this annotation is its `from` argument.

The following method annotation can be used to establish a method postcondition that ensures that a certain sequence has a minimum length:

@EnsuresMinLenIf(String[] expression, boolean result, int targetValue) If the method with this annotation returns the given boolean value, then the given expression (or all the given expressions) is a sequence with at least `targetValue` elements.

8.5 Sequences of the same length

The Index Checker determines whether two or more sequences have the same length. This enables it to verify that all the indexing operations are safe in code like the following:

```
boolean lessThan(double[] arr1, double @SameLen("#1") [] arr2) {
    for (int i = 0; i < arr1.length; i++) {
        if (arr1[i] < arr2[i]) {
            return true;
        } else if (arr1[i] > arr2[i]) {
```

Figure 8.2: The type hierarchy for arrays of equal length ("a" and "b" are assumed to be in-scope sequences). Qualifiers written in gray should never be written in source code; they are used internally by the type system.

```

    return false;
  }
}
return false;
}

```

When needed, you can specify which sequences have the same length using the following type qualifiers (Figure 8.2):

@SameLen(String[] names) An expression with this type represents a sequence that has the same length as the other sequences named in `names`. In general, @SameLen types that have non-intersecting sets of names are *not* subtypes of each other. However, if at least one sequence is named by both types, the types are actually the same, because all the named sequences must have the same length.

@PolySameLen indicates qualifier polymorphism. For a description of qualifier polymorphism, see Section 26.2.

@SameLenUnknown No information is known about which other sequences have the same length as this one. This is the top type, and programmers should never need to write it.

@SameLenBottom This is the bottom type, and programmers should rarely need to write it. `null` has this type.

8.6 Binary search indices

The JDK's `Arrays.binarySearch` method returns either where the value was found, or a negative value indicating where the value could be inserted. The Search Index Checker represents this concept.

The Search Index Checker's type hierarchy (Figure 8.3) has four type qualifiers:

@SearchIndexFor(String[] names) An expression with this type represents an integer that could have been produced by calling `Arrays.binarySearch`: for each array `a` specified in the annotation, the annotated integer is between `-a.length-1` and `a.length-1`, inclusive

@NegativeIndexFor(String[] names) An expression with this type represents a "negative index" that is between `a.length-1` and `-1`, inclusive; that is, a value that is both a `@SearchIndex` and is negative. Applying the bitwise complement operator (`~`) to an expression of this type produces an expression of type `@IndexOrHigh`.

@SearchIndexBottom This is the bottom type, and programmers should rarely need to write it.

@SearchIndexUnknown No information is known about whether this integer is a search index. This is the top type, and programmers should rarely need to write it.

Figure 8.3: The type hierarchy for the Index Checker's internal type system that captures information about the results of calls to `Arrays.binarySearch`.

8.7 Substring indices

The methods `String.indexOf` and `String.lastIndexOf` return an index of a given substring within a given string, or -1 if no such substring exists. The index `i` returned from `receiver.indexOf(substring)` satisfies the following property, which is stated here in three equivalent ways:

```

i == -1 || ( i >= 0          && i <= receiver.length() - substring.length()          )
i == -1 || ( @NonNegative && @LTLengthOf(value="receiver", offset="substring.length()-1") )
@SubstringIndexFor(value="receiver", offset="substring.length()-1")

```

The return type of methods `String.indexOf` and `String.lastIndexOf` has the annotation `@SubstringIndexFor(value="this", offset="#1.length()-1")`. This allows writing code such as the following with no warnings from the Index Checker:

```

public static String removeSubstring(String original, String removed) {
    int i = original.indexOf(removed);
    if (i != -1) {
        return original.substring(0, i) + original.substring(i + removed.length());
    }
    return original;
}

```

The `@SubstringIndexFor` annotation is implemented in a Substring Index Checker that runs together with the Index Checker and has its own type hierarchy (Figure 8.4) with three type qualifiers:

@SubstringIndexFor(String[] value, String[] offset) An expression with this type represents an integer that could have been produced by calling `String.indexOf`: the annotated integer is either -1, or it is non-negative and is less than or equal to `receiver.length - offset` (where the sequence `receiver` and the offset `offset` are corresponding elements of the annotation's arguments).

@SubstringIndexBottom This is the bottom type, and programmers should rarely need to write it.

@SubstringIndexUnknown No information is known about whether this integer is a substring index. This is the top type, and programmers should rarely need to write it.

Figure 8.4: The type hierarchy for the Substring Index Checker, which captures information about the results of calls to `String.indexOf` and `String.lastIndexOf`.

8.7.1 The need for the `@SubstringIndexFor` annotation

No other annotation supported by the Index Checker precisely represents the possible return values of methods `String.indexOf` and `String.lastIndexOf`. The reason is the methods' special cases for empty strings and for failed matches.

Consider the result `i` of `receiver.indexOf(substring)`:

- `i` is `@GTENegativeOne`, because `i >= -1`.
- `i` is `@LTEqLengthOf("receiver")`, because `i <= receiver.length()`.
- `i` is not `@IndexOrLow("receiver")`, because for `receiver = ""`, `substring = ""`, `i = 0`, the property `i >= -1 && i < receiver.length()` does not hold.
- `i` is not `@IndexOrHigh("receiver")`, because for `receiver = ""`, `substring = "b"`, `i = -1`, the property `i >= 0 && i <= receiver.length()` does not hold.
- `i` is not `@LTLengthOf(value = "receiver", offset = "substring.length()-1")`, because for `receiver = ""`, `substring = "abc"`, `i = -1`, the property `i + substring.length() - 1 < receiver.length()` does not hold.

The last annotation in the list above, `@LTLengthOf(value = "receiver", offset = "substring.length()-1")`, is the correct and precise upper bound for all values of `i` except `-1`. The offset expresses the fact that we can add `substring.length()` to this index and still get a valid index for `receiver`. That is useful for type-checking code that adds the length of the substring to the found index, in order to obtain the rest of the string. However, the upper bound applies only after the index is explicitly checked not to be `-1`:

```

int i = receiver.indexOf(substring);
// i is @GTENegativeOne and @LTEqLengthOf("receiver")
// i is not @LTLengthOf(value = "receiver", offset = "substring.length()-1")
if (i != -1) {
    // i is @NonNegative and @LTLengthOf(value = "receiver", offset = "substring.length()-1")
    int j = i + substring.length();
    // j is @IndexOrHigh("receiver")
    return receiver.substring(j); // this call is safe
}
  
```

The property of the result of `indexOf` cannot be expressed by any combination of lower-bound (Section 8.2) and upper-bound (Section 8.3) annotations, because the upper-bound annotations apply independently of the lower-bound annotations, but in this case, the upper bound `i <= receiver.length() - substring.length()` holds only if `i >= 0`. Therefore, to express this property and make the example type-check without false positives, a new annotation such as `@SubstringIndexFor(value = "receiver", offset = "substring.length()-1")` is necessary.

8.8 Inequalities

The Index Checker estimates which expression's values are less than other expressions' values.

@LessThan(String[] values) An expression with this type has a value that is less than the value of each expression listed in `values`. The expressions in `values` must be composed of final or effectively final variables and constants.

@LessThanUnknown There is no information about the value of an expression this type relative to other expressions. This is the top type, and should not be written by the programmer.

@LessThanBottom This is the bottom type for the less than type system. It should never need to be written by the programmer.

8.9 Annotating fixed-size data structures

The Index Checker has built-in support for Strings and arrays. You can add support for additional fixed-size data structures by writing annotations. This allows the Index Checker to typecheck the data structure's implementation and to typecheck uses of the class.

This section gives an example: a fixed-length collection.

```
/** ArrayWrapper is a fixed-size generic collection. */
public class ArrayWrapper<T> {
    private final Object @SameLen("this") [] delegate;

    @SuppressWarnings("index") // constructor creates object of size @SameLen(this) by definition
    ArrayWrapper(@NonNegative int size) {
        delegate = new Object[size];
    }

    public @LengthOf("this") int size() {
        return delegate.length;
    }

    public void set(@IndexFor("this") int index, T obj) {
        delegate[index] = obj;
    }

    @SuppressWarnings("unchecked") // required for normal Java compilation due to unchecked cast
    public T get(@IndexFor("this") int index) {
        return (T) delegate[index];
    }
}
```

The Index Checker treats methods annotated with `@LengthOf("this")` as the length of a sequence like `arr.length` for arrays and `str.length()` for strings.

With these annotations, client code like the following typechecks with no warnings:

```
public static void clearIndex1(ArrayWrapper<? extends Object> a, @IndexFor("#1") int i) {
    a.set(i, null);
}

public static void clearIndex2(ArrayWrapper<? extends Object> a, int i) {
    if (0 <= i && i < a.size()) {
```

```
        a.set(i, null);  
    }  
}
```

Chapter 9

Fake Enum Checker for fake enumerations

The Fake Enum Checker, or Fenum Checker, enables you to define a type alias or typedef, in which two different sets of values have the same representation (the same Java type) but are not allowed to be used interchangeably. It is also possible to create a typedef using the Subtyping Checker (Chapter 24, page 138), and that approach is sometimes more appropriate.

One common use for the Fake Enum Checker is the *fake enumeration pattern* (Section 9.6). For example, consider this code adapted from Android’s `IntDef` documentation:

```
@NavigationMode int NAVIGATION_MODE_STANDARD = 0;
@NavigationMode int NAVIGATION_MODE_LIST = 1;
@NavigationMode int NAVIGATION_MODE_TABS = 2;

@NavigationMode int getNavigationMode();

void setNavigationMode(@NavigationMode int mode);
```

The Fake Enum Checker can issue a compile-time warning if the programmer ever tries to call `setNavigationMode` with an `int` that is not a `@NavigationMode int`.

The Fake Enum Checker gives the same safety guarantees as a true enumeration type or typedef, but retaining backward-compatibility with interfaces that use existing Java types. You can apply `fenum` annotations to any Java type, including all primitive types and also reference types. Thus, you could use it (for example) to represent floating-point values between 0 and 1, or `Strings` with some particular characteristic. (Note that the Fake Enum Checker does not let you create a shorter alias for a long type name, as a real typedef would if Java supported it.)

As explained in Section 9.1, you can either define your own `fenum` annotations, such as `@NavigationMode` above, or you can use the `@Fenum` type qualifier with a string argument. Figure 9.1 shows part of the type hierarchy for the Fenum type system.

9.1 Fake enum annotations

The Fake Enum Checker supports two ways to introduce a new fake enum (fenum):

1. Introduce your own specialized `fenum` annotation with code like this in file `MyFenum.java`:

```
package myPackage.qual;

import java.lang.annotation.Documented;
import java.lang.annotation.ElementType;
import java.lang.annotation.Retention;
import java.lang.annotation.RetentionPolicy;
```

Figure 9.1: Partial type hierarchy for the Fenum type system. There are two forms of fake enumeration annotations — above, illustrated by `@Fenum("A")` and `@FenumC`. See Section 9.1 for descriptions of how to introduce both types of fenums. The type qualifiers in gray (`@FenumTop`, `@FenumUnqualified`, and `@FenumBottom`) should never be written in source code; they are used internally by the type system. `@FenumUnqualified` is the default qualifier for unannotated types, except for upper bounds which default to `@FenumTop`.

```
import java.lang.annotation.Target;
import org.checkerframework.checker.fenum.qual.FenumTop;
import org.checkerframework.framework.qual.SubtypeOf;

@Documented
@Retention(RetentionPolicy.RUNTIME)
@Target({ElementType.TYPE_USE, ElementType.TYPE_PARAMETER})
@SubtypeOf(FenumTop.class)
public @interface MyFenum {}
```

You only need to adapt the italicized package, annotation, and file names in the example.

Note that all custom annotations must have the `@Target({ElementType.TYPE_USE})` meta-annotation. See section 32.5.1.

2. Use the provided `@Fenum` annotation, which takes a `String` argument to distinguish different fenums or type aliases. For example, `@Fenum("A")` and `@Fenum("B")` are two distinct type qualifiers.

The first approach allows you to define a short, meaningful name suitable for your project, whereas the second approach allows quick prototyping.

9.2 What the Fenum Checker checks

The Fenum Checker ensures that unrelated types are not mixed. All types with a particular fenum annotation, or `@Fenum(...)` with a particular `String` argument, are disjoint from all unannotated types and from all types with a different fenum annotation or `String` argument.

The checker ensures that only compatible fenum types are used in comparisons and arithmetic operations (if applicable to the annotated type).

It is the programmer's responsibility to ensure that fields with a fenum type are properly initialized before use. Otherwise, one might observe a `null` reference or zero value in the field of a fenum type. (The Nullness Checker (Chapter 3, page 27) can prevent failure to initialize a reference variable.)

9.3 Running the Fenum Checker

The Fenum Checker can be invoked by running the following commands.

- If you define your own annotation(s), provide the name(s) of the annotation(s) through the `-Aquals` option, using a comma-no-space-separated notation:

```
javac -classpath /full/path/to/myProject/bin:/full/path/to/myLibrary/bin \
      -processor org.checkerframework.checker.fenum.FenumChecker \
      -Aquals=myPackage.qual.MyFenum MyFile.java ...
```

The annotations listed in `-Aquals` must be accessible to the compiler during compilation in the classpath. In other words, they must already be compiled (and, typically, be on the javac classpath) before you run the Fenum Checker with javac. It is not sufficient to supply their source files on the command line.

You can also provide the fully-qualified paths to a set of directories that contain the annotations through the `-AqualDirs` option, using a colon-no-space-separated notation. For example:

```
javac -classpath /full/path/to/myProject/bin:/full/path/to/myLibrary/bin \
      -processor org.checkerframework.checker.fenum.FenumChecker \
      -AqualDirs=/full/path/to/myProject/bin:/full/path/to/myLibrary/bin MyFile.java ...
```

Note that in these two examples, the compiled class file of the `myPackage.qual.MyFenum` annotation must exist in either the `myProject/bin` directory or the `myLibrary/bin` directory. The following placement of the class file will work with the above commands:

```
.../myProject/bin/myPackage/qual/MyFenum.class
```

The two options can be used at the same time to provide groups of annotations from directories, and individually named annotations.

- If your code uses the `@Fenum` annotation, you do not need the `-Aquals` or `-AqualDirs` option:

```
javac -processor org.checkerframework.checker.fenum.FenumChecker MyFile.java ...
```

For an example of running the Fake Enum Checker on Android code, see <https://github.com/karlicoss/checker-fenum-android-demo>.

9.4 Suppressing warnings

One example of when you need to suppress warnings is when you initialize the fenum constants to literal values. To remove this warning message, add a `@SuppressWarnings` annotation to either the field or class declaration, for example:

```
@SuppressWarnings("fenum:assignment.type.incompatible") // initialization of fake enums
class MyConsts {
    public static final @Fenum("A") int ACONST1 = 1;
    public static final @Fenum("A") int ACONST2 = 2;
}
```

9.5 Example

The following example introduces two fenums in class `TestStatic` and then performs a few typical operations.

```
@SuppressWarnings("fenum:assignment.type.incompatible") // initialization of fake enums
public class TestStatic {
    public static final @Fenum("A") int ACONST1 = 1;
    public static final @Fenum("A") int ACONST2 = 2;

    public static final @Fenum("B") int BCONST1 = 4;
    public static final @Fenum("B") int BCONST2 = 5;
}

class FenumUser {
    @Fenum("A") int state1 = TestStatic.ACONST1; // ok
    @Fenum("B") int state2 = TestStatic.ACONST1; // Incompatible fenums forbidden!
```

```

void fenumArg(@Fenum("A") int p) {}

void fenumTest() {
    statel = 4;                // Direct use of value forbidden!
    statel = TestStatic.BCONST1; // Incompatible fenums forbidden!
    statel = TestStatic.ACONST2; // ok

    fenumArg(5);              // Direct use of value forbidden!
    fenumArg(TestStatic.BCONST1); // Incompatible fenums forbidden!
    fenumArg(TestStatic.ACONST1); // ok
}
}

```

Also, see the example project in the `docs/examples/fenum-extension` directory.

9.6 The fake enumeration pattern

Java's `enum` keyword lets you define an enumeration type: a finite set of distinct values that are related to one another but are disjoint from all other types, including other enumerations. Before enums were added to Java, there were two ways to encode an enumeration, both of which are error-prone:

the fake enum pattern a set of `int` or `String` constants (as often found in older C code).

the typesafe enum pattern a class with private constructor.

Sometimes you need to use the fake enum pattern, rather than a real enum or the typesafe enum pattern. One reason is backward-compatibility. A public API that predates Java's `enum` keyword may use `int` constants; it cannot be changed, because doing so would break existing clients. For example, Java's JDK still uses `int` constants in the AWT and Swing frameworks, and Android also uses `int` constants rather than Java enums. Another reason is performance, especially in environments with limited resources. Use of an `int` instead of an object can reduce code size, memory requirements, and run time.

In cases when code has to use the fake enum pattern, the Fake Enum Checker, or Fenum Checker, gives the same safety guarantees as a true enumeration type. The developer can introduce new types that are distinct from all values of the base type and from all other fake enums. Fenums can be introduced for primitive types as well as for reference types.

Chapter 10

Tainting Checker

The Tainting Checker prevents certain kinds of trust errors. A *tainted*, or untrusted, value is one that comes from an arbitrary, possibly malicious source, such as user input or unvalidated data. In certain parts of your application, using a tainted value can compromise the application’s integrity, causing it to crash, corrupt data, leak private data, etc.

For example, a user-supplied pointer, handle, or map key should be validated before being dereferenced. As another example, a user-supplied string should not be concatenated into a SQL query, lest the program be subject to a SQL injection attack. A location in your program where malicious data could do damage is called a *sensitive sink*.

A program must “sanitize” or “untaint” an untrusted value before using it at a sensitive sink. There are two general ways to untaint a value: by checking that it is innocuous/legal (e.g., it contains no characters that can be interpreted as SQL commands when pasted into a string context), or by transforming the value to be legal (e.g., quoting all the characters that can be interpreted as SQL commands). A correct program must use one of these two techniques so that tainted values never flow to a sensitive sink. The Tainting Checker ensures that your program does so.

If the Tainting Checker issues no warning for a given program, then no tainted value ever flows to a sensitive sink. However, your program is not necessarily free from all trust errors. As a simple example, you might have forgotten to annotate a sensitive sink as requiring an untainted type, or you might have forgotten to annotate untrusted data as having a tainted type.

To run the Tainting Checker, supply the `-processor TaintingChecker` command-line option to `javac`.

10.1 Tainting annotations

The Tainting type system uses the following annotations:

- `@Untainted` indicates a type that includes only untainted (trusted) values.
- `@Tainted` indicates a type that may include tainted (untrusted) or untainted (trusted) values. `@Tainted` is a supertype of `@Untainted`. It is the default qualifier.
- `@PolyTainted` is a qualifier that is polymorphic over tainting (see Section 26.2).

10.2 Tips on writing `@Untainted` annotations

Most programs are designed with a boundary that surrounds sensitive computations, separating them from untrusted values. Outside this boundary, the program may manipulate malicious values, but no malicious values ever pass the boundary to be operated upon by sensitive computations.

In some programs, the area outside the boundary is very small: values are sanitized as soon as they are received from an external source. In other programs, the area inside the boundary is very small: values are sanitized only immediately before being used at a sensitive sink. Either approach can work, so long as every possibly-tainted value is sanitized before it reaches a sensitive sink.

Once you determine the boundary, annotating your program is easy: put `@Tainted` outside the boundary, `@Untainted` inside, and `@SuppressWarnings("tainting")` at the validation or sanitization routines that are used at the boundary.

The Tainting Checker's standard default qualifier is `@Tainted` (see Section 27.5 for overriding this default). This is the safest default, and the one that should be used for all code outside the boundary (for example, code that reads user input). You can set the default qualifier to `@Untainted` in code that may contain sensitive sinks.

The Tainting Checker does not know the intended semantics of your program, so it cannot warn you if you mis-annotate a sensitive sink as taking `@Tainted` data, or if you mis-annotate external data as `@Untainted`. So long as you correctly annotate the sensitive sinks and the places that untrusted data is read, the Tainting Checker will ensure that all your other annotations are correct and that no undesired information flows exist.

As an example, suppose that you wish to prevent SQL injection attacks. You would start by annotating the `Statement` class to indicate that the `execute` operations may only operate on untainted queries (Chapter 31 describes how to annotate external libraries):

```
public boolean execute(@Untainted String sql) throws SQLException;
public boolean executeUpdate(@Untainted String sql) throws SQLException;
```

10.3 `@Tainted` and `@Untainted` can be used for many purposes

The `@Tainted` and `@Untainted` annotations have only minimal built-in semantics. In fact, the Tainting Checker provides only a small amount of functionality beyond the Subtyping Checker (Chapter 24). This lack of hard-coded behavior has two consequences. The first consequence is that the annotations can serve many different purposes, such as:

- Prevent SQL injection attacks: `@Tainted` is external input, `@Untainted` has been checked for SQL syntax.
- Prevent cross-site scripting attacks: `@Tainted` is external input, `@Untainted` has been checked for JavaScript syntax.
- Prevent information leakage: `@Tainted` is secret data, `@Untainted` may be displayed to a user.

The second consequence is that the Tainting Checker is not useful unless you annotate the appropriate sources, sinks, and untainting/sanitization routines.

If you want more specialized semantics, or you want to annotate multiple types of tainting (for example, HTML and SQL) in a single program, then you can copy the definition of the Tainting Checker to create a new annotation and checker with a more specific name and semantics. You will change the copy to rename the annotations, and you will annotate libraries and/or your code to identify sources, sinks, and validation/sanitization routines. See Chapter 32 for more details.

10.4 A caution about polymorphism and side effects

Misuse of polymorphism can lead to unsoundness with the Tainting Checker and other similar information flow checkers. To understand the potential problem, consider the `append` function in `java.lang.StringBuffer`:

```
public StringBuffer append(StringBuffer this, String toAppend);
```

Given these declarations:

```
@Tainted StringBuffer tsb;
@Tainted String ts;
@Untainted StringBuffer usb;
@Untainted String us;
```

both of these invocations should be legal:

```
tsb.append(ts);
usb.append(us);
```

That suggests that perhaps the function should be annotated as polymorphic:

```
// UNSOUND annotation -- do not do this!
public @PolyTainted StringBuffer append(@PolyTainted StringBuffer this, @PolyTainted String toAppend);
```

The problem with the above annotation is that it permits the undesirable invocation:

```
usb.append(ts); // illegal invocation
```

This invocation is permitted because, in the expression, all `@PolyTainted` annotations on formal parameters are instantiated to `@Tainted`, the top annotation, and each argument is a subtype of the corresponding formal parameter.

Beware this problem both in code you write, and also in annotated libraries (such as stub files).

(Side note: if `append` were purely functional (had no side effects and returned a new `StringBuffer`) the method call would be acceptable, because the return type is instantiated to `@Tainted StringBuffer` for the expression `usb.append(ts)`. However, the `append` method works via side-effect, and only returns a reference to the buffer as a convenience for writing “fluent” client code.)

Chapter 11

Regex Checker for regular expression syntax

The Regex Checker prevents, at compile-time, use of syntactically invalid regular expressions and access of invalid capturing groups.

A regular expression, or regex, is a pattern for matching certain strings of text. In Java, a programmer writes a regular expression as a string. The syntax of regular expressions is complex, so it is easy to make a mistake. It is also easy to accidentally use a regex feature from another language that is not supported by Java (see section “Comparison to Perl 5” in the `Pattern` Javadoc). These problems cause run-time errors.

Regular expressions in Java also have capturing groups, which are delimited by parentheses and allow for extraction from text. If a programmer uses an incorrect index (larger than the number of capturing groups), an `IndexOutOfBoundsException` is thrown.

The Regex Checker warns about these problems at compile time, guaranteeing that your program does not crash due to incorrect use of regular expressions.

For further details, including case studies, see a paper about the Regex Checker [SDE12].

To run the Regex Checker, supply the `-processor org.checkerframework.checker.regex.RegexChecker` command-line option to `javac`.

11.1 Regex annotations

These qualifiers make up the Regex type system:

@Regex indicates that the run-time value is a valid regular expression `String`. If the optional parameter is supplied to the qualifier, then the number of capturing groups in the regular expression is at least that many. If not provided, the parameter defaults to 0. For example, if an expression’s type is `@Regex(1) String`, then its run-time value could be `"colo(u?)r"` or `"(brown|beige)"` but not `"colou?r"` nor a non-regex string such as `"1) first point"`.

@PolyRegex indicates qualifier polymorphism (see Section 26.2).

The subtyping hierarchy of the Regex Checker’s qualifiers is shown in Figure 11.1.

11.2 Annotating your code with @Regex

11.2.1 Implicit qualifiers

The Regex Checker adds implicit qualifiers, reducing the number of annotations that must appear in your code (see Section 27.4). If a `String` literal is a valid regex, the checker implicitly adds the `@Regex` qualifier with the argument

Figure 11.1: The subtyping relationship of the Regex Checker’s qualifiers. The type qualifiers are applicable to `CharSequence` and its subtypes. Because the parameter to a `@Regex` qualifier is at least the number of capturing groups in a regular expression, a `@Regex` qualifier with more capturing groups is a subtype of a `@Regex` qualifier with fewer capturing groups. Qualifiers in gray are used internally by the type system but should never be written by a programmer.

```

public @Regex String parenthesize(@Regex String regex) {
    return "(" + regex + "; // Even though the parentheses are not @Regex Strings,
    // the whole expression is a @Regex String
}

```

Figure 11.2: An example of the Regex Checker’s support for concatenation of non-regular-expression Strings to produce valid regular expression Strings.

set to the correct number of capturing groups. The Regex Checker allows the `null` literal to be assigned to any type qualified with the `Regex` qualifier.

11.2.2 Capturing groups

The Regex Checker validates that a legal capturing group number is passed to `Matcher`’s `group`, `start` and `end` methods. To do this, the type of `Matcher` must be qualified with a `@Regex` annotation with the number of capturing groups in the regular expression. This is handled implicitly by the Regex Checker for local variables (see Section 27.7), but you may need to add `@Regex` annotations with a capturing group count to `Pattern` and `Matcher` fields and parameters.

11.2.3 Concatenation of partial regular expressions

In general, concatenating a non-regular-expression String with any other string yields a non-regular-expression String. The Regex Checker can sometimes determine that concatenation of non-regular-expression Strings will produce valid regular expression Strings. For an example see Figure 11.2.

```
String regex = getRegexFromUser();
if (!RegexUtil.isRegex(regex)) {
    throw new RuntimeException("Error parsing regex " + regex, RegexUtil.regexException(regex));
}
Pattern p = Pattern.compile(regex);
```

Figure 11.3: Example use of `RegexUtil` methods.

11.2.4 Testing whether a string is a regular expression

Sometimes, the Regex Checker cannot infer whether a particular expression is a regular expression — and sometimes your code cannot either! In these cases, you can use the `isRegex` method to perform such a test, and other helper methods to provide useful error messages. A common use is for user-provided regular expressions (such as ones passed on the command-line). Figure 11.3 gives an example of the intended use of the `RegexUtil` methods.

`RegexUtil.isRegex` returns `true` if its argument is a valid regular expression.

`RegexUtil.regexError` returns a `String` error message if its argument is not a valid regular expression, or `null` if its argument is a valid regular expression.

`RegexUtil.regexException` returns the `PatternSyntaxException` that `Pattern.compile(String)` throws when compiling an invalid regular expression. It returns `null` if its argument is a valid regular expression.

An additional version of each of these methods is also provided that takes an additional group count parameter. The `RegexUtil.isRegex` method verifies that the argument has at least the given number of groups. The `RegexUtil.regexError` and `RegexUtil.regexException` methods return a `String` error message and `PatternSyntaxException`, respectively, detailing why the given `String` is not a syntactically valid regular expression with at least the given number of capturing groups.

If you detect that a `String` is not a valid regular expression but would like to report the error higher up the call stack (potentially where you can provide a more detailed error message) you can throw a `RegexUtil.CheckedPatternSyntaxException`. This exception is functionally the same as a `PatternSyntaxException` except it is checked to guarantee that the error will be handled up the call stack. For more details, see the Javadoc for `RegexUtil.CheckedPatternSyntaxException`.

To use the `RegexUtil` class, the `checker-qual.jar` file must be on the classpath at run time.

11.2.5 Suppressing warnings

If you are positive that a particular string that is being used as a regular expression is syntactically valid, but the Regex Checker cannot conclude this and issues a warning about possible use of an invalid regular expression, then you can use the `RegexUtil.asRegex` method to suppress the warning.

You can think of this method as a cast: it returns its argument unchanged, but with the type `@Regex String` if it is a valid regular expression. It throws an error if its argument is not a valid regular expression, but you should only use it when you are sure it will not throw an error.

There is an additional `RegexUtil.asRegex` method that takes a capturing group parameter. This method works the same as described above, but returns a `@Regex String` with the parameter on the annotation set to the value of the capturing group parameter passed to the method.

The use case shown in Figure 11.3 should support most cases so the `asRegex` method should be used rarely.

Chapter 12

Format String Checker

The Format String Checker prevents use of incorrect format strings in format methods such as `System.out.printf` and `String.format`.

The Format String Checker warns you if you write an invalid format string, and it warns you if the other arguments are not consistent with the format string (in number of arguments or in their types). Here are examples of errors that the Format String Checker detects at compile time. Section 12.3 provides more details.

```
String.format("%y", 7);           // error: invalid format string

String.format("%d", "a string"); // error: invalid argument type for %d

String.format("%d %s", 7);       // error: missing argument for %s
String.format("%d", 7, 3);       // warning: unused argument 3
String.format("{0}", 7);        // warning: unused argument 7, because {0} is wrong syntax
```

To run the Format String Checker, supply the `-processor org.checkerframework.checker.formatter.FormatterChecker` command-line option to `javac`.

12.1 Formatting terminology

Printf-style formatting takes as an argument a *format string* and a list of arguments. It produces a new string in which each *format specifier* has been replaced by the corresponding argument. The format specifier determines how the format argument is converted to a string. A format specifier is introduced by a `%` character. For example, `String.format("The %s is %d.", "answer", 42)` yields "The answer is 42.". "The %s is %d." is the format string, "%s" and "%d" are the format specifiers; "answer" and 42 are format arguments.

12.2 Format String Checker annotations

The `@Format` qualifier on a string type indicates a valid format string. A programmer rarely writes the `@Format` annotation, as it is inferred for string literals. A programmer may need to write it on fields and on method signatures.

The `@Format` qualifier is parameterized with a list of conversion categories that impose restrictions on the format arguments. Conversion categories are explained in more detail in Section 12.2.1. The type qualifier for `"%d %f"` is for example `@Format({INT, FLOAT})`.

Consider the below `printFloatAndInt` method. Its parameter must be a format string that can be used in a format method, where the first format argument is “float-like” and the second format argument is “integer-like”. The type of its parameter, `@Format({FLOAT, INT}) String`, expresses that contract.

Figure 12.1: The Format String Checker type qualifier hierarchy. The type qualifiers are applicable to `CharSequence` and its subtypes. The figure does not show the subtyping rules among different `@Format(...)` qualifiers; see Section 12.2.2.

```

void printFloatAndInt (@Format({FLOAT, INT}) String fs) {
    System.out.printf(fs, 3.1415, 42);
}

printFloatAndInt("Float %f, Number %d"); // OK
printFloatAndInt("Float %f");           // error
  
```

Figure 12.1 shows all the type qualifiers. The annotations other than `@Format` are only used internally and cannot be written in your code. `@InvalidFormat` indicates an invalid format string — that is, a string that cannot be used as a format string. For example, the type of `"%y"` is `@InvalidFormat String`. `@FormatBottom` is the type of the null literal. `@UnknownFormat` is the default that is applied to strings that are not literals and on which the user has not written a `@Format` annotation.

There is also a `@FormatMethod` annotation; see Section 12.5.

12.2.1 Conversion Categories

Given a format specifier, only certain format arguments are compatible with it, depending on its “conversion” — its last, or last two, characters. For example, in the format specifier `"%d"`, the conversion `d` restricts the corresponding format argument to be “integer-like”:

```

String.format("%d", 5);           // OK
String.format("%d", "hello");    // error
  
```

Many conversions enforce the same restrictions. A set of restrictions is represented as a *conversion category*. The “integer like” restriction is for example the conversion category `INT`. The following conversion categories are defined in the `ConversionCategory` enumeration:

GENERAL imposes no restrictions on a format argument’s type. Applicable for conversions `b`, `B`, `h`, `H`, `s`, `S`.

CHAR requires that a format argument represents a Unicode character. Specifically, `char`, `Character`, `byte`, `Byte`, `short`, and `Short` are allowed. `int` or `Integer` are allowed if `Character.isValidCodePoint(argument)` would return `true` for the format argument. (The Format String Checker permits any `int` or `Integer` without issuing a warning or error — see Section 12.3.2.) Applicable for conversions `c`, `C`.

INT requires that a format argument represents an integral type. Specifically, `byte`, `Byte`, `short`, `Short`, `int` and `Integer`, `long`, `Long`, and `BigInteger` are allowed. Applicable for conversions `d`, `o`, `x`, `X`.

FLOAT requires that a format argument represents a floating-point type. Specifically, `float`, `Float`, `double`, `Double`, and `BigDecimal` are allowed. Surprisingly, integer values are not allowed. Applicable for conversions `e`, `E`, `f`, `g`, `G`, `a`, `A`.

TIME requires that a format argument represents a date or time. Specifically, `long`, `Long`, `Calendar`, and `Date` are allowed. Applicable for conversions `t`, `T`.

UNUSED imposes no restrictions on a format argument. This is the case if a format argument is not used as replacement for any format specifier. "%2\$s" for example ignores the first format argument.

Further, all conversion categories accept `null`.

The same format argument may serve as a replacement for multiple format specifiers. Until now, we have assumed that the format specifiers simply consume format arguments left to right. But there are two other ways for a format specifier to select a format argument:

- `n$` specifies a one-based index `n`. In the format string "%2\$s", the format specifier selects the second format argument.
- The `<flag` references the format argument that was used by the previous format specifier. In the format string "%d %<d" for example, both format specifiers select the first format argument.

In the following example, the format argument must be compatible with both conversion categories, and can therefore be neither a `Character` nor a `long`.

```
format("Char %1$c, Int %1$d", (int)42);           // OK
format("Char %1$c, Int %1$d", new Character(42)); // error
format("Char %1$c, Int %1$d", (long)42);         // error
```

Only three additional conversion categories are needed represent all possible intersections of previously-mentioned conversion categories:

NULL is used if no object of any type can be passed as parameter. In this case, the only legal value is `null`. The format string "%1\$f %1\$c", for example requires that the first format argument be `null`. Passing a value such as 4 or 4.2 would lead to an exception.

CHAR_AND_INT is used if a format argument is restricted by a CHAR and a INT conversion category ($\text{CHAR} \cap \text{INT}$).

INT_AND_TIME is used if a format argument is restricted by an INT and a TIME conversion category ($\text{INT} \cap \text{TIME}$).

All other intersections lead to already existing conversion categories. For example, $\text{GENERAL} \cap \text{CHAR} = \text{CHAR}$ and $\text{UNUSED} \cap \text{GENERAL} = \text{GENERAL}$.

Figure 12.2 summarizes the subset relationship among all conversion categories.

12.2.2 Subtyping rules for @Format

Here are the subtyping rules among different @Format qualifiers. It is legal to:

- use a format string with a weaker (less restrictive) conversion category than required.
- use a format string with fewer format specifiers than required. Although this is legal a warning is issued because most occurrences of this are due to programmer error.

The following example shows the subtyping rules in action:

```
@Format({FLOAT, INT}) String f;

f = "%f %d";           // OK
f = "%s %d";           // OK, %s is weaker than %f
f = "%f";              // warning: last argument is ignored
f = "%f %d %s";        // error: too many arguments
f = "%d %d";           // error: %d is not weaker than %f

String.format(f, 0.8, 42);
```

Figure 12.2: The subset relationship among conversion categories.

12.3 What the Format String Checker checks

If the Format String Checker issues no errors, it provides the following guarantees:

1. The following guarantees hold for every format method invocation:
 - (a) The format method's first parameter (or second if a `Locale` is provided) is a valid format string (or null).
 - (b) A warning is issued if one of the format string's conversion categories is `UNUSED`.
 - (c) None of the format string's conversion categories is `NULL`.
2. If the format arguments are passed to the format method as `varargs`, the Format String Checker guarantees the following additional properties:
 - (a) No fewer format arguments are passed than required by the format string.
 - (b) A warning is issued if more format arguments are passed than required by the format string.
 - (c) Every format argument's type satisfies its conversion category's restrictions.
3. If the format arguments are passed to the format method as an array, a warning is issued by the Format String Checker.

Following are examples for every guarantee:

```

String.format("%d", 42); // OK
String.format(Locale.GERMAN, "%d", 42); // OK
String.format(new Object()); // error (1a)
String.format("%y"); // error (1a)
String.format("%2$s", "unused", "used"); // warning (1b)
String.format("%1$d %1$f", 5.5); // error (1c)
String.format("%1$d %1$f %d", null, 6); // error (1c)
String.format("%s"); // error (2a)
String.format("%s", "used", "ignored"); // warning (2b)
String.format("%c", 4.2); // error (2c)
String.format("%c", (String)null); // error (2c)
String.format("%1$d %1$f", new Object[]{1}); // warning (3)
String.format("%s", new Object[]{"hello"}); // warning (3)
  
```

12.3.1 Possible false alarms

There are three cases in which the Format String Checker may issue a warning or error, even though the code cannot fail at run time. (These are in addition to the general conservatism of a type system: code may be correct because of application invariants that are not captured by the type system.) In each of these cases, you can rewrite the code, or you can manually check it and write a `@SuppressWarnings` annotation if you can reason that the code is correct.

Case 1b: Unused format arguments. It is legal to provide more arguments than are required by the format string; Java ignores the extras. However, this is an uncommon case. In practice, a mismatch between the number of format specifiers and the number of format arguments is usually an error.

Case 1c: Format arguments that can only be `null`. It is legal to write a format string that permits only null arguments and throws an exception for any other argument. An example is `String.format("%1$d %1$f", null)`. The Format String Checker forbids such a format string. If you should ever need such a format string, simply replace the problematic format specifier with `"null"`. For example, you would replace the call above by `String.format("null null")`.

Case 3: Array format arguments. The Format String Checker performs no analysis of arrays, only of varargs invocations. It is better style to use varargs when possible.

12.3.2 Possible missed alarms

The Format String Checker helps prevent bugs by detecting, at compile time, which invocations of format methods will fail. While the Format String Checker finds most of these invocations, there are cases in which a format method call will fail even though the Format String Checker issued neither errors nor warnings. These cases are:

1. The format string is `null`. Use the Nullness Checker to prevent this.
2. A format argument's `toString` method throws an exception.
3. A format argument implements the `Formattable` interface and throws an exception in the `formatTo` method.
4. A format argument's conversion category is `CHAR` or `CHAR_AND_INT`, and the passed value is an `int` or `Integer`, and `Character.isValidCodePoint(argument)` returns `false`.

The following examples illustrate these limitations:

```
class A {
    public String toString() {
        throw new Error();
    }
}

class B implements Formattable {
    public void formatTo(Formatter fmt, int f,
        int width, int precision) {
        throw new Error();
    }
}

// The checker issues no errors or warnings for the
// following illegal invocations of format methods.
String.format(null); // NullPointerException (1)
String.format("%s", new A()); // Error (2)
String.format("%s", new B()); // Error (3)
String.format("%c", (int)-1); // IllegalFormatCodePointException (4)
```

12.4 Implicit qualifiers

The Format String Checker adds implicit qualifiers, reducing the number of annotations that must appear in your code (see Section 27.4). The checker implicitly adds the `@Format` qualifier with the appropriate conversion categories to any `String` literal that is a valid format string.

12.5 @FormatMethod

Your project may contain methods that forward their arguments to a format method. Consider for example the following `log` method:

```
@FormatMethod
void log(String format, Object... args) {
    if (enabled) {
        logfile.print(indent_str);
        logfile.printf(format , args);
    }
}
```

You should annotate such a method with the `@FormatMethod` annotation, which indicates that the `String` argument is a format string for the remaining arguments.

12.6 Testing whether a format string is valid

The Format String Checker automatically determines whether each `String` literal is a valid format string or not. When a string is computed or is obtained from an external resource, then the string must be trusted or tested.

One way to test a string is to call the `FormatUtil.asFormat` method to check whether the format string is valid and its format specifiers match certain conversion categories. If this is not the case, `asFormat` raises an exception. Your code should catch this exception and handle it gracefully.

The following code examples may fail at run time, and therefore they do not type check. The type-checking errors are indicated by comments.

```
Scanner s = new Scanner(System.in);
String fs = s.next();
System.out.printf(fs, "hello", 1337);           // error: fs is not known to be a format string

Scanner s = new Scanner(System.in);
@Format({GENERAL, INT}) String fs = s.next(); // error: fs is not known to have the given type
System.out.printf(fs, "hello", 1337);         // OK
```

The following variant does not throw a run-time error, and therefore passes the type-checker:

```
Scanner s = new Scanner(System.in);
String format = s.next()
try {
    format = FormatUtil.asFormat(format, GENERAL, INT);
} catch (IllegalFormatException e) {
    // Replace this by your own error handling.
    System.err.println("The user entered the following invalid format string: " + format);
    System.exit(2);
}
// fs is now known to be of type: @Format({GENERAL, INT}) String
System.out.printf(format, "hello", 1337);
```

To use the `FormatUtil` class, the `checker-qual.jar` file must be on the classpath at run time.

Chapter 13

Internationalization Format String Checker (I18n Format String Checker)

The Internationalization Format String Checker, or I18n Format String Checker, prevents use of incorrect `i18n` format strings.

If the I18n Format String Checker issues no warnings or errors, then `MessageFormat.format` will raise no error at run time. “I18n” is short for “internationalization” because there are 18 characters between the “i” and the “n”.

Here are the examples of errors that the I18n Format Checker detects at compile time.

```
// Warning: the second argument is missing.
MessageFormat.format("{0} {1}", 3.1415);
// String argument cannot be formatted as Time type.
MessageFormat.format("{0, time}", "my string");
// Invalid format string: unknown format type: thyme.
MessageFormat.format("{0, thyme}", new Date());
// Invalid format string: missing the right brace.
MessageFormat.format("{0", new Date());
// Invalid format string: the argument index is not an integer.
MessageFormat.format("{0.2, time}", new Date());
// Invalid format string: "#.#.#" subformat is invalid.
MessageFormat.format("{0, number, #.#.#}", 3.1415);
```

For instructions on how to run the Internationalization Format String Checker, see Section 13.6.

The Internationalization Checker or I18n Checker (Chapter 14.2, page 104) has a different purpose. It verifies that your code is properly internationalized: any user-visible text should be obtained from a localization resource and all keys exist in that resource.

13.1 Internationalization Format String Checker annotations

The `MessageFormat` documentation specifies the syntax of the `i18n` format string.

These are the qualifiers that make up the I18n Format String type system. Figure 13.1 shows their subtyping relationships.

@I18nFormat represents a valid `i18n` format string. For example, `@I18nFormat({GENERAL, NUMBER, UNUSED, DATE})` is a legal type for `"{0}{1, number} {3, date}"`, indicating that when the format string is used, the first argument should be of `GENERAL` conversion category, the second argument should be of `NUMBER` conversion category, and so on. Conversion categories such as `GENERAL` are described in Section 13.2.

Figure 13.1: The Internationalization Format String Checker type qualifier hierarchy. The type qualifiers are applicable to `CharSequence` and its subtypes. The figure does not show the subtyping rules among different `@I18nFormat(...)` qualifiers; see Section 13.2. All `@I18nFormatFor` annotations are unrelated by subtyping. The qualifiers in gray are used internally by the checker and should never be written by a programmer.

@I18nFormatFor indicates that the qualified type is a valid i18n format string for use with some array of values. For example, `@I18nFormatFor("#2")` indicates that the string can be used to format the contents of the second parameter array. The argument is a Java expression whose syntax is explained in Section 27.8. An example of its use is:

```
static void method(@I18nFormatFor("#2") String format, Object... args) {
    // the body may use the parameters like this:
    MessageFormat.format(format, args);
}

method("{0, number} {1}", 3.1415, "A string"); // OK
// error: The string "hello" cannot be formatted as a Number.
method("{0, number} {1}", "hello", "goodbye");
```

@I18nInvalidFormat represents an invalid i18n format string. Programmers are not allowed to write this annotation. It is only used internally by the type checker.

@I18nUnknownFormat represents any string. The string might or might not be a valid i18n format string. Programmers are not allowed to write this annotation.

@I18nFormatBottom indicates that the value is definitely null. Programmers are not allowed to write this annotation.

13.2 Conversion categories

In a message string, the optional second element within the curly braces is called a *format type* and must be one of `number`, `date`, `time`, and `choice`. These four format types correspond to different conversion categories. `date` and `time` correspond to *DATE* in the conversion categories figure. `choice` corresponds to *NUMBER*. The format type restricts what arguments are legal. For example, a date argument is not compatible with the `number` format type, i.e., `MessageFormat.format("{0, number}", new Date())` will throw an exception.

The I18n Checker represents the possible arguments via *conversion categories*. A conversion category defines a set of restrictions or a subtyping rule.

Figure 13.2 summarizes the subset relationship among all conversion categories.

13.3 Subtyping rules for @I18nFormat

Here are the subtyping rules among different `@I18nFormat` qualifiers. It is legal to:

- use a format string with a weaker (less restrictive) conversion category than required.
- use a format string with fewer format specifiers than required. Although this is legal a warning is issued because most occurrences of this are due to programmer error.

Figure 13.2: The subset relationship among i18n conversion categories.

The following example shows the subtyping rules in action:

```

@I18nFormat({NUMBER, DATE}) String f;

f = "{0, number, #.##} {1, date}"; // OK
f = "{0, number} {1}";             // OK, GENERAL is weaker (less restrictive) than DATE
f = "{0} {1, date}";              // OK, GENERAL is weaker (less restrictive) than NUMBER
f = "{0, number}";                // warning: last argument is ignored
f = "{0}";                         // warning: last argument is ignored
f = "{0, number} {1, number}";     // error: NUMBER is stronger (more restrictive) than DATE
f = "{0} {1} {2}";                // error: too many arguments
  
```

The conversion categories are:

UNUSED indicates an unused argument. For example, in `MessageFormat.format("{0, number} {2, number}", 3.14, "Hello", 2.718)`, the second argument `Hello` is unused. Thus, the conversion categories for the format, 0, number 2, number, is (NUMBER, UNUSED, NUMBER).

GENERAL means that any value can be supplied as an argument.

DATE is applicable for date, time, and number types. An argument needs to be of `Date`, `Time`, or `Number` type or a subclass of them, including `Timestamp` and the classes listed immediately below.

NUMBER means that the argument needs to be of `Number` type or a subclass: `Number`, `AtomicInteger`, `AtomicLong`, `BigDecimal`, `BigInteger`, `Byte`, `Double`, `Float`, `Integer`, `Long`, `Short`.

13.4 What the Internationalization Format String Checker checks

The Internationalization Format String Checker checks calls to the i18n formatting method `MessageFormat.format` and guarantees the following:

1. The checker issues a warning for the following cases:

(a) There are missing arguments from what is required by the format string.

```
MessageFormat.format("{0, number} {1, number}", 3.14); // Output: 3.14 {1}
```

(b) More arguments are passed than what is required by the format string.

```
MessageFormat.format("{0, number}", 1, new Date());
MessageFormat.format("{0, number} {0, number}", 3.14, 3.14);
```

This does not cause an error at run time, but it often indicates a programmer mistake. If it is intentional, then you should suppress the warning (see Chapter 28).

- (c) Some argument is an array of objects.

```
MessageFormat.format("{0, number} {1}", array);
```

The checker cannot verify whether the format string is valid, so the checker conservatively issues a warning. This is a limitation of the Internationalization Format String Checker.

2. The checker issues an error for the following cases:

- (a) The format string is invalid.

- Unmatched braces.

```
MessageFormat.format("{0, time", new Date());
```

- The argument index is not an integer or is negative.

```
MessageFormat.format("{0.2, time}", new Date());
```

```
MessageFormat.format("{-1, time}", new Date());
```

- Unknown format type.

```
MessageFormat.format("{0, foo}", 3.14);
```

- Missing a format style required for choice format.

```
MessageFormat.format("{0, choice}", 3.14);
```

- Wrong format style.

```
MessageFormat.format("{0, time, number}", 3.14);
```

- Invalid subformats.

```
MessageFormat.format("{0, number, #.#.#}", 3.14)
```

- (b) Some argument's type doesn't satisfy its conversion category.

```
MessageFormat.format("{0, number}", new Date());
```

The Checker also detects illegal assignments: assigning a non-format-string or an incompatible format string to a variable declared as containing a specific type of format string. For example,

```
@I18nFormat({GENERAL, NUMBER}) String format;
// OK.
format = "{0} {1, number}";
// OK, GENERAL is weaker (less restrictive) than NUMBER.
format = "{0} {1}";
// OK, it is legal to have fewer arguments than required (less restrictive).
// But the warning will be issued instead.
format = "{0}";

// Error, the format string is stronger (more restrictive) than the specifiers.
format = "{0} {1} {2}";
// Error, the format string is more restrictive. NUMBER is a subtype of GENERAL.
format = "{0, number} {1, number}";
```

13.5 Resource files

A programmer rarely writes an `i18n` format string literally. (The examples in this chapter show that for simplicity.) Rather, the `i18n` format strings are read from a resource file. The program chooses a resource file at run time depending on the locale (for example, different resource files for English and Spanish users).

For example, suppose that the `resource1.properties` file contains

```
key1 = The number is {0, number}.
```

Then code such as the following:

```
String formatPattern = ResourceBundle.getBundle("resource1").getString("key1");
System.out.println(MessageFormat.format(formatPattern, 2.2361));
```

will output “The number is 2.2361.” A different resource file would contain `key1 = El número es {0, number}`.

When you run the I18n Format String Checker, you need to indicate which resource file it should check. If you change the resource file or use a different resource file, you should re-run the checker to ensure that you did not make an error. The I18n Format String Checker supports two types of resource files: `ResourceBundles` and property files. The example above shows use of resource bundles. For more about checking property files, see Chapter 14, page 103.

13.6 Running the Internationalization Format Checker

The checker can be invoked by running one of the following commands (with the whole command on one line).

- Using `ResourceBundles`:

```
javac -processor org.checkerframework.checker.i18nformatter.I18nFormatterChecker -Abundlenames=MyResource MyFile.java
```

- Using property files:

```
javac -processor org.checkerframework.checker.i18nformatter.I18nFormatterChecker -Apropfiles=MyResource.properties MyFile.java
```

- Not using a property file. Use this if the programmer hard-coded the format patterns without loading them from a property file.

```
javac -processor org.checkerframework.checker.i18nformatter.I18nFormatterChecker MyFile.java
```

13.7 Testing whether a string has an i18n format type

In the case that the checker cannot infer the i18n format type of a string, you can use the `I18nFormatUtil.hasFormat` method to define the type of the string in the scope of a conditional statement.

`I18nFormatUtil.hasFormat` returns `true` if the given string has the given i18n format type.

For an example, see Section 13.8.

13.8 Examples of using the Internationalization Format Checker

- Using `MessageFormat.format`.

```
// suppose the bundle "MyResource" contains: key1={0, number} {1, date}
String value = ResourceBundle.getBundle("MyResource").getString("key1");
MessageFormat.format(value, 3.14, new Date()); // OK
// error: incompatible types in argument; found String, expected number
MessageFormat.format(value, "Text", new Date());
```

- Using the `I18nFormatUtil.hasFormat` method to check whether a format string has particular conversion categories.

```
void test1(String format) {
    if (I18nFormatUtil.hasFormat(format, I18nConversionCategory.GENERAL,
        I18nConversionCategory.NUMBER)) {
        MessageFormat.format(format, "Hello", 3.14); // OK
        // error: incompatible types in argument; found String, expected number
        MessageFormat.format(format, "Hello", "Bye");
        // error: missing arguments; expected 2 but 1 given
        MessageFormat.format(format, "Bye");
        // error: too many arguments; expected 2 but 3 given
        MessageFormat.format(format, "A String", 3.14, 3.14);
    }
}
```

```
    }  
}
```

- Using `@I18nFormatFor` to ensure that an argument is a particular type of format string.

```
static void method(@I18nFormatFor("#2") String f, Object... args) {...}  
  
// OK, MessageFormat.format(...) would return "3.14 Hello greater than one"  
method("{0, number} {1} {2, choice,0#zero|1#one|1<greater than one}",  
        3.14, "Hello", 100);  
  
// error: incompatible types in argument; found String, expected number  
method("{0, number} {1}", "Bye", "Bye");
```

- Annotating a string with `@I18nFormat`.

```
@I18nFormat({I18nConversionCategory.DATE}) String;  
s1 = "{0}";  
s1 = "{0, number}";           // error: incompatible types in assignment
```

Chapter 14

Property File Checker

The Property File Checker ensures that a property file or resource bundle (both of which act like maps from keys to values) is only accessed with valid keys. Accesses without a valid key either return `null` or a default value, which can lead to a `NullPointerException` or hard-to-trace behavior. The Property File Checker (Section 14.1, page 103) ensures that the used keys are found in the corresponding property file or resource bundle.

We also provide two specialized checkers. An Internationalization Checker (Section 14.2, page 104) verifies that code is properly internationalized. A Compiler Message Key Checker (Section 14.3, page 104) verifies that compiler message keys used in the Checker Framework are declared in a property file. This is an example of a simple specialization of the property file checker, and the Checker Framework source code shows how it is used.

It is easy to customize the property key checker for other related purposes. Take a look at the source code of the Compiler Message Key Checker and adapt it for your purposes.

14.1 General Property File Checker

The general Property File Checker ensures that a resource key is located in a specified property file or resource bundle.

The annotation `@PropertyKey` indicates that the qualified `CharSequence` is a valid key found in the property file or resource bundle. You do not need to annotate `String` literals. The checker looks up every `String` literal in the specified property file or resource bundle, and adds annotations as appropriate.

If you pass a `CharSequence` (including `String`) variable to be eventually used as a key, you also need to annotate all these variables with `@PropertyKey`.

The checker can be invoked by running the following command:

```
javac -processor org.checkerframework.checker.propkey.PropertyKeyChecker
      -Abundlenames=MyResource MyFile.java ...
```

You must specify the resources, which map keys to strings. The checker supports two types of resource: resource bundles and property files. You can specify one or both of the following two command-line options:

1. `-Abundlenames=resource_name`
resource_name is the name of the resource to be used with `ResourceBundle.getBundle()`. The checker uses the default `Locale` and `ClassLoader` in the compilation system. (For a tutorial about `ResourceBundles`, see <https://docs.oracle.com/javase/tutorial/i18n/resbundle/concept.html>.) Multiple resource bundle names are separated by colons `':'`.
2. `-Apropfiles=prop_file`
prop_file is the name of a properties file that maps keys to values. The file format is described in the Javadoc for `Properties.load()`. Multiple files are separated by colons `':'`.

14.2 Internationalization Checker (I18n Checker)

The Internationalization Checker, or I18n Checker, verifies that your code is properly internationalized. Internationalization is the process of designing software so that it can be adapted to different languages and locales without needing to change the code. Localization is the process of adapting internationalized software to specific languages and locales.

Internationalization is sometimes called i18n, because the word starts with “i”, ends with “n”, and has 18 characters in between. Localization is similarly sometimes abbreviated as l10n.

The checker focuses on one aspect of internationalization: user-visible text should be presented in the user’s own language, such as English, French, or German. This is achieved by looking up keys in a localization resource, which maps keys to user-visible text. For instance, one version of a resource might map "CANCEL_STRING" to "Cancel", and another version of the same resource might map "CANCEL_STRING" to "Abbrechen".

There are other aspects to localization, such as formatting of dates (3/5 vs. 5/3 for March 5), that the checker does not check.

The Internationalization Checker verifies these two properties:

1. Any user-visible text should be obtained from a localization resource. For example, `String` literals should not be output to the user.
2. When looking up keys in a localization resource, the key should exist in that resource. This check catches incorrect or misspelled localization keys.

If you use the Internationalization Checker, you may want to also use the Internationalization Format String Checker, or I18n Format String Checker (Chapter 13). It verifies that internationalization format strings are well-formed and used with arguments of the proper type, so that `MessageFormat.format` does not fail at run time.

14.2.1 Internationalization annotations

The Internationalization Checker supports two annotations:

1. `@Localized`: indicates that the qualified `CharSequence` is a message that has been localized and/or formatted with respect to the used locale.
2. `@LocalizableKey`: indicates that the qualified `CharSequence` or `Object` is a valid key found in the localization resource. This annotation is a specialization of the `@PropertyKey` annotation, that gets checked by the general Property Key Checker.

You may need to add the `@Localized` annotation to more methods in the JDK or other libraries, or in your own code.

14.2.2 Running the Internationalization Checker

The Internationalization Checker can be invoked by running the following command:

```
javac -processor org.checkerframework.checker.i18n.I18nChecker -Abundlenames=MyResource MyFile.java ...
```

You must specify the localization resource, which maps keys to user-visible text. Like the general Property Key Checker, the Internationalization Checker supports two types of localization resource: `ResourceBundles` using the `-Abundlenames=resource_name` option or property files using the `-Apropfiles=prop_file` option.

14.3 Compiler Message Key Checker

The Checker Framework uses compiler message keys to output error messages. These keys are substituted by localized strings for user-visible error messages. Using keys instead of the localized strings in the source code enables easier testing, as the expected error keys can stay unchanged while the localized strings can still be modified. We use the Compiler Message Key Checker to ensure that all internal keys are correctly localized. Instead of using the Property File Checker, we use a specialized checker, giving us more precise documentation of the intended use of `Strings`.

The single annotation used by this checker is `@CompilerMessageKey`. The Checker Framework is completely annotated; for example, class `org.checkerframework.framework.source.Result` uses `@CompilerMessageKey` in methods `failure` and `warning`. For most users of the Checker Framework there will be no need to annotate any Strings, as the checker looks up all String literals and adds annotations as appropriate.

The Compiler Message Key Checker can be invoked by running the following command:

```
javac -processor org.checkerframework.checker.compilermsgs.CompilerMessagesChecker  
      -Apropfiles=messages.properties MyFile.java ...
```

You must specify the resource, which maps compiler message keys to user-visible text. The checker supports the same options as the general property key checker. Within the Checker Framework we only use property files, so the `-Apropfiles=prop_file` option should be used.

Chapter 15

Signature String Checker for string representations of types

The Signature String Checker, or Signature Checker for short, verifies that string representations of types and signatures are used correctly.

Java defines multiple different string representations for types (see Section 15.1), and it is easy to misuse them or to miss bugs during testing. Using the wrong string format leads to a run-time exception or an incorrect result. This is a particular problem for fully qualified and binary names, which are nearly the same — they differ only for nested classes and arrays.

15.1 Signature annotations

Java defines six formats for the string representation of a type. There is an annotation for each of these representations. Figure 15.1 shows how they are related; examples appear in a table below.

@FullyQualifiedName A *fully qualified name* (JLS §6.7), such as `package.Outer.Inner`, is used in Java code and in messages to the user.

@ClassGetName The type representation used by the `Class.getName()`, `Class.forName(String)`, and `Class.forName(String, boolean, ClassLoader)` methods. This format is: for any non-array type, the binary name; and for any array type, a format like the `FieldDescriptor` field descriptor, but using “.” where the field descriptor uses “/”. See examples below.

@FieldDescriptor A *field descriptor* (JVMS §4.3.2), such as `Lpackage/Outer$Inner;`, is used in a `.class` file’s constant pool, for example to refer to other types. It abbreviates primitive types and array types. It uses internal form (binary names, but with / instead of .; see JVMS §4.2) for class names. See examples below.

@BinaryName A *binary name* (JLS §13.1), such as `package.Outer$Inner`, is the conceptual name of a type in its own `.class` file.

@InternalForm The *internal form* (JVMS §4.2), such as `package/Outer$Inner`, is how a class name is actually represented in its own `.class` file. It is also known as the “syntax of binary names that appear in class file structures”. It is the same as the binary name, but with periods (.) replaced by slashes (/). Programmers more often use the binary name, leaving the internal form as a JVM implementation detail.

@ClassGetSimpleName The type representation returned by the `Class.getSimpleName()` method. This format is not required by any method in the JDK, so you will rarely write it in source code. The string can be empty. This is not the same as the “simple name” defined in (JLS §6.2), which is the same as `@Identifier`.

@FqBinaryName An extension of binary name format to represent primitives and arrays. It is like `@FullyQualifiedName`, but using “\$” instead of “.” to separate nested classes from their containing classes. For example, `"pkg.Outer$Inner"` or `"pkg.Outer$Inner[][]"` or `"int[]"`.

Figure 15.1: Partial type hierarchy for the Signature type system, showing string representations of a Java type. The type qualifiers are applicable to `CharSequence` and its subtypes. Programmers usually only need to write the boldfaced qualifiers; other qualifiers are included to improve the internal handling of String literals.

Other type qualifiers are the intersection of two or more qualifiers listed above; for example, a `@BinaryNameInUnnamedPackage` is a string that is a valid internal form *and* a valid binary name. A programmer should never or rarely use these qualifiers, and you can ignore them as implementation details of the Signature Checker, though you might occasionally see them in an error message. These qualifiers exist to give literals sufficiently precise types that they can be used in any appropriate context.

Java also defines other string formats for a type: qualified names (JLS §6.2) and canonical names (JLS §6.7). The Signature Checker does not include annotations for these.

Here are examples of the supported formats:

fully qualified name	<code>Class.getName</code>	field descriptor	binary name	internal form	<code>Class.getSimpleName</code>
<code>int</code>	<code>int</code>	<code>I</code>	<i>n/a for primitive type</i>	<i>n/a for primitive type</i>	<code>int</code>
<code>int[][]</code>	<code>[[I</code>	<code>[[I</code>	<i>n/a for array type</i>	<i>n/a for array type</i>	<code>int[][]</code>
<code>MyClass</code>	<code>MyClass</code>	<code>LMyClass;</code>	<code>MyClass</code>	<code>MyClass</code>	<code>MyClass</code>
<code>MyClass[]</code>	<code>[LMyClass;</code>	<code>[LMyClass;</code>	<i>n/a for array type</i>	<i>n/a for array type</i>	<code>MyClass[]</code>
<i>n/a for anonymous class</i>	<code>MyClass\$22</code>	<code>LMyClass\$22;</code>	<code>MyClass\$22</code>	<code>MyClass\$22</code>	<i>(empty string)</i>
<i>n/a for array of anon. class</i>	<code>[LMyClass\$22;</code>	<code>[LMyClass\$22;</code>	<i>n/a for array type</i>	<i>n/a for array type</i>	<code>[]</code>
<code>java.lang.Integer</code>	<code>java.lang.Integer</code>	<code>Ljava/lang/Integer;</code>	<code>java.lang.Integer</code>	<code>java/lang/Integer</code>	<code>Integer</code>
<code>java.lang.Integer[]</code>	<code>[Ljava.lang.Integer;</code>	<code>[Ljava/lang/Integer;</code>	<i>n/a for array type</i>	<i>n/a for array type</i>	<code>Integer[]</code>
<code>pkg.Outer.Inner</code>	<code>pkg.Outer\$Inner</code>	<code>Lpkg/Outer\$Inner;</code>	<code>pkg.Outer\$Inner</code>	<code>pkg/Outer\$Inner</code>	<code>Inner</code>
<code>pkg.Outer.Inner[]</code>	<code>[Lpkg.Outer\$Inner;</code>	<code>[Lpkg/Outer\$Inner;</code>	<i>n/a for array type</i>	<i>n/a for array type</i>	<code>Inner[]</code>
<i>n/a for anonymous class</i>	<code>pkg.Outer\$22</code>	<code>Lpkg/Outer\$22;</code>	<code>pkg.Outer\$22</code>	<code>pkg/Outer\$22</code>	<i>(empty string)</i>
<i>n/a for array of anon. class</i>	<code>[Lpkg.Outer\$22;</code>	<code>[Lpkg/Outer\$22;</code>	<i>n/a for array type</i>	<i>n/a for array type</i>	<code>[]</code>

Java defines one format for the string representation of a method signature:

@MethodDescriptor A *method descriptor* (JVMS §4.3.3) identifies a method's signature (its parameter and return types), just as a field descriptor identifies a type. The method descriptor for the method

```
Object mymethod(int i, double d, Thread t)
```

is

```
(IDLjava/lang/Thread;)Ljava/lang/Object;
```

15.2 What the Signature Checker checks

Certain methods in the JDK, such as `Class.forName`, are annotated indicating the type they require. The Signature Checker ensures that clients call them with the proper arguments. The Signature Checker does not reason about string operations such as concatenation, substring, parsing, etc.

To run the Signature Checker, supply the `-processor org.checkerframework.checker.signature.SignatureChecker` command-line option to `javac`.

Chapter 16

GUI Effect Checker

One of the most prevalent GUI-related bugs is *invalid UI update* or *invalid thread access*: accessing the UI directly from a background thread.

Most GUI frameworks (including Android, AWT, Swing, and SWT) create a single distinguished thread — the UI event thread — that handles all GUI events and updates. To keep the interface responsive, any expensive computation should be offloaded to *background threads* (also called *worker threads*). If a background thread accesses a UI element such as a JPanel (by calling a JPanel method or reading/writing a field of JPanel), the GUI framework raises an exception that terminates the program. To fix the bug, the background thread should send a request to the UI thread to perform the access on its behalf.

It is difficult for a programmer to remember which methods may be called on which thread(s). The GUI Effect Checker solves this problem. The programmer annotates each method to indicate whether:

- It accesses no UI elements (and may run on any thread); such a method is said to have the “safe effect”.
- It may access UI elements (and must run on the UI thread); such a method is said to have the “UI effect”.

The GUI Effect Checker verifies these effects and statically enforces that UI methods are only called from the correct thread. A method with the safe effect is prohibited from calling a method with the UI effect.

For example, the effect system can reason about when method calls must be dispatched to the UI thread via a message such as `Display.syncExec`.

```
@SafeEffect
public void calledFromBackgroundThreads(JLabel l) {
    l.setText("Foo");          // Error: calling a @UIEffect method from a @SafeEffect method
    Display.syncExec(new Runnable {
        @UIEffect // inferred by default
        public void run() {
            l.setText("Bar"); // OK: accessing JLabel from code run on the UI thread
        }
    });
}
```

The GUI Effect Checker’s annotations fall into three categories:

- effect annotations on methods (Section 16.1),
- class or package annotations controlling the default effect (Section 16.4), and
- *effect-polymorphism*: code that works for both the safe effect and the UI effect (Section 16.5).

16.1 GUI effect annotations

There are two primary GUI effect annotations:

- `@SafeEffect` is a method annotation marking code that must not access UI objects.
- `@UIEffect` is a method annotation marking code that may access UI objects. Most UI object methods (e.g., methods of `JPanel`) are annotated as `@UIEffect`.

`@SafeEffect` is a sub-effect of `@UIEffect`, in that it is always safe to call a `@SafeEffect` method anywhere it is permitted to call a `@UIEffect` method. We write this relationship as

`@SafeEffect < @UIEffect`

16.2 What the GUI Effect Checker checks

The GUI Effect Checker ensures that only the UI thread accesses UI objects. This prevents GUI errors such as invalid UI update and invalid thread access.

The GUI Effect Checker issues errors in the following cases:

- A `@UIEffect` method is invoked by a `@SafeEffect` method.
- Method declarations violate subtyping restrictions: a supertype declares a `@SafeEffect` method, and a subtype annotates an overriding version as `@UIEffect`.

Additionally, if a method implements or overrides a method in two supertypes (two interfaces, or an interface and parent class), and those supertypes give different effects for the methods, the GUI Effect Checker issues a warning (not an error).

16.3 Running the GUI Effect Checker

The GUI Effect Checker can be invoked by running the following command:

```
javac -processor org.checkerframework.checker.guieffect.GuiEffectChecker MyFile.java ...
```

16.4 Annotation defaults

The default method annotation is `@SafeEffect`, since most code in most programs is not related to the UI. This also means that typically, code that is unrelated to the UI need not be annotated at all.

The GUI Effect Checker provides three primary ways to change the default method effect for a class or package:

- `@UIType` is a class annotation that makes the effect for unannotated methods in that class default to `@UIEffect`. (See also `@UI` in Section 16.5.2.)
- `@UIPackage` is a *package* annotation, that makes the effect for unannotated methods in that package default to `@UIEffect`. It is not transitive; a package nested inside a package marked `@UIPackage` does not inherit the changed default.
- `@SafeType` is a class annotation that makes the effect for unannotated methods in that class default to `@SafeEffect`. Because `@SafeEffect` is already the default effect, `@SafeType` is only useful for class types inside a package marked `@UIPackage`.

There is one other place where the default annotation is not automatically `@SafeEffect`: anonymous inner classes. Since anonymous inner classes exist primarily for brevity, it would be unfortunate to spoil that brevity with extra annotations. By default, an anonymous inner class method that overrides or implements a method of the parent type inherits that method's effect. For example, an anonymous inner class implementing an interface with method `@UIEffect void m()` need not explicitly annotate its implementation of `m()`; the implementation will inherit the parent's effect. Methods of the anonymous inner class that are not inherited from a parent type follow the standard defaulting rules.

16.5 Polymorphic effects

Sometimes a type is reused for both UI-specific and background-thread work. A good example is the `Runnable` interface, which is used both for creating new background threads (in which case the `run()` method must have the `@SafeEffect`) and for sending code to the UI thread to execute (in which case the `run()` method may have the `@UIEffect`). But the declaration of `Runnable.run()` may have only one effect annotation in the source code. How do we reconcile these conflicting use cases?

Effect-polymorphism permits a type to be used for both UI and non-UI purposes. It is similar to Java's generics in that you define, then use, the effect-polymorphic type. Recall that to *define* a generic type, you write a type parameter such as `<T>` and use it in the body of the type definition; for example, `class List<T> { ... T get() {...} ... }`. To *instantiate* a generic type, you write its name along with a type argument; for example, `List<Date> myDates;`.

16.5.1 Defining an effect-polymorphic type

To declare that a class is effect-polymorphic, annotate its definition with `@PolyUIType`. To use the effect variable in the class body, annotate a method with `@PolyUIEffect`. It is an error to use `@PolyUIEffect` in a class that is not effect-polymorphic.

Consider the following example:

```
@PolyUIType
public interface Runnable {
    @PolyUIEffect
    void run();
}
```

This declares that class `Runnable` is parameterized over one generic effect, and that when `Runnable` is instantiated, the effect argument will be used as the effect for the `run` method.

16.5.2 Using an effect-polymorphic type

To instantiate an effect-polymorphic type, write one of these three type qualifiers before a use of the type:

- `@AlwaysSafe` instantiates the type's effect to `@SafeEffect`.
- `@UI` instantiates the type's effect to `@UIEffect`. *Additionally*, it changes the default method effect for the class to `@UIEffect`.
- `@PolyUI` instantiates the type's effect to `@PolyUIEffect` for the same instantiation as the current (containing) class. For example, this is the qualifier of the receiver `this` inside a method of a `@PolyUIType` class, which is how one method of an effect-polymorphic class may call an effect-polymorphic method of the same class.

As an example:

```
@AlwaysSafe Runnable s = ...;    s.run();    // s.run() is @SafeEffect
@PolyUI Runnable p = ...;        p.run();    // p.run() is @PolyUIEffect (context-dependent)
@UI Runnable u = ...;            u.run();    // u.run() is @UIEffect
```

It is an error to apply an effect instantiation qualifier to a type that is not effect-polymorphic.

Note that no annotation is required on the anonymous class declaration itself (e.g. `new Runnable() { ... }` does not require a type use annotation, although the variable, field, or argument it ends up being assigned to might). Instead, the GUI Effect Checker will infer the effect qualifier based on the method being called from within the members of that specific anonymous class.

16.5.3 Subclassing a specific instantiation of an effect-polymorphic type

Sometimes you may wish to subclass a specific instantiation of an effect-polymorphic type, just as you may extend `List<String>`.

To do this, simply place the effect instantiation qualifier by the name of the type you are defining, e.g.:

```
@UI
public class UIRunnable extends Runnable {...}
@AlwaysSafe
public class SafeRunnable extends Runnable {...}
```

The GUI Effect Checker will automatically apply the qualifier to all classes and interfaces the class being defined extends or implements. (This means you cannot write a class that is a subtype of a `@AlwaysSafe Foo` and a `@UI Bar`, but this has not been a problem in our experience.)

16.5.4 Subtyping with polymorphic effects

With three effect annotations, we must extend the static sub-effecting relationship:

$$\text{@SafeEffect} \prec \text{@PolyUIEffect} \prec \text{@UIEffect}$$

This is the correct sub-effecting relation because it is always safe to call a `@SafeEffect` method (whether from an effect-polymorphic method or a UI method), and a `@UIEffect` method may safely call any other method.

This induces a subtyping hierarchy on type qualifiers:

$$\text{@AlwaysSafe} \prec \text{@PolyUI} \prec \text{@UI}$$

This is sound because a method instantiated according to any qualifier will always be safe to call in place of a method instantiated according to one of its super-qualifiers. This allows clients to pass “safer” instances of some object type to a given method.

Effect polymorphism and arguments

Sometimes it is useful to have `@PolyUI` parameters on a method. As a trivial example, this permits us to specify an identity method that works for both `@UI Runnable` and `@AlwaysSafe Runnable`:

```
public @PolyUI Runnable id(@PolyUI Runnable r) {
    return r;
}
```

This use of `@PolyUI` will be handled as is standard for polymorphic qualifiers in the Checker Framework (see Section 26.2).

`@PolyUIEffect` methods should generally not use `@PolyUI` arguments: it is permitted by the framework, but its interaction with inheritance is subtle, and may not behave as you would hope.

The shortest explanation is this: `@PolyUI` arguments may only be overridden by `@PolyUI` arguments, even though the implicitly `@PolyUI receiver` may be overridden with a `@AlwaysSafe receiver`.

As noted earlier (Section 26.1.6), Java’s generics are invariant — `A<X>` is a subtype of `B<Y>` only if `X` is identical to `Y`. Class-level use of `@PolyUI` behaves slightly differently. Marking a type declaration `@PolyUIType` is conceptually equivalent to parameterizing the type by some `E extends Effect`. But in this view, `Runnable<SafeEffect>` (really `@AlwaysSafe Runnable`) would be considered a subtype of `Runnable<UIEffect>` (really `@UI Runnable`), as explained earlier in this section. Java’s generics do not permit this, which is called *covariant* subtyping in the effect parameter. Permitting it for all generics leads to problems where a type system can miss errors. Java solves this by making all generics invariant, which rejects more programs than strictly necessary, but leads to an easy-to-explain limitation. For this checker, covariant subtyping of effect parameters is very important: being able to pass an `@AlwaysSafe Runnable` in place of a `@UI Runnable` is extremely useful. Since we need to allow some cases for flexibility, but need to reject other cases to avoid missing errors, the distinction is a bit more subtle for this checker.

Consider this small example (warning: the following is rejected by the GUI Effect Checker):

```

@PolyUIType
public interface Dispatcher {
    @PolyUIEffect
    void dispatch(@PolyUI Runnable toRun);
}
@SafeType
public class SafeDispatcher implements Dispatcher {
    @Override
    public void dispatch(@AlwaysSafe Runnable toRun) {
        runOnBackgroundThread(toRun);
    }
}

```

This may initially seem like harmless code to write, which simply specializes the implicit effect parameter from `Dispatcher` in the `SafeDispatcher` implementation. However, the way method effect polymorphism is implemented is by implicitly making the receiver of a `@PolyUIEffect` method — the object on which the method is invoked — `@PolyUI`. So if the definitions above were permitted, the following client code would be possible:

```

@AlwaysSafe SafeDispatcher s = ...;
@UI Runnable uitask = ...;
s.dispatch(uitask);

```

At the call to `dispatch`, the Checker Framework is free to consider `s` as its supertype, `@UI SafeDispatcher`. This permits the framework to choose the same qualifier for both the (implicit) receiver use of `@PolyUI` and the `toRun` argument to `Dispatcher.dispatch`, passing the checker. But this code would then pass a UI-thread-only task to a method which should only accept background thread tasks — exactly what the checker should prevent!

To resolve this, the GUI Effect Checker rejects the definitions above, specifically the `@AlwaysSafe` on `SafeDispatcher.dispatch`'s parameter, which would need to remain `@PolyUI`.

A subtlety of the code above is that the receiver for `SafeDispatcher.dispatch` is also overridden, switching from a `@PolyUI` receiver to a `@Safe` receiver. That change is permissible. But when that is done, the polymorphic arguments may no longer be interchangeable with the receiver.

16.6 References

The ECOOP 2013 paper “JavaUI: Effects for Controlling UI Object Access” includes some case studies on the checker’s efficacy, including descriptions of the relatively few false warnings we encountered. It also contains a more formal description of the effect system. You can obtain the paper at:

<https://homes.cs.washington.edu/~mernst/pubs/gui-thread-ecoop2013-abstract.html>

Chapter 17

Units Checker

For many applications, it is important to use the correct units of measurement for primitive types. For example, NASA's Mars Climate Orbiter (cost: \$327 million) was lost because of a discrepancy between use of the metric unit Newtons and the imperial measure Pound-force.

The *Units Checker* ensures consistent usage of units. For example, consider the following code:

```
@m int meters = 5 * UnitsTools.m;  
@s int secs = 2 * UnitsTools.s;  
@mPERs int speed = meters / secs;
```

Due to the annotations `@m` and `@s`, the variables `meters` and `secs` are guaranteed to contain only values with meters and seconds as units of measurement. Utility class `UnitsTools` provides constants with which unqualified integer are multiplied to get values of the corresponding unit. The assignment of an unqualified value to `meters`, as in `meters = 99`, will be flagged as an error by the Units Checker.

The division `meters/secs` takes the types of the two operands into account and determines that the result is of type meters per second, signified by the `@mPERs` qualifier. We provide an extensible framework to define the result of operations on units.

17.1 Units annotations

The checker currently supports three varieties of units annotations: kind annotations (`@Length`, `@Mass`, ...), the SI units (`@m`, `@kg`, ...), and polymorphic annotations (`@PolyUnit`).

Kind annotations can be used to declare what the expected unit of measurement is, without fixing the particular unit used. For example, one could write a method taking a `@Length` value, without specifying whether it will take meters or kilometers. The following kind annotations are defined:

```
@Acceleration  
@Angle  
@Area  
@Current  
@Length  
@Luminance  
@Mass  
@Speed  
@Substance  
@Temperature  
@Time
```

For each kind of unit, the corresponding SI unit of measurement is defined:

1. For `@Acceleration`: Meter Per Second Square `@mPERs2`
2. For `@Angle`: Radians `@radians`, and the derived unit Degrees `@degrees`
3. For `@Area`: the derived units square millimeters `@mm2`, square meters `@m2`, and square kilometers `@km2`
4. For `@Current`: Ampere `@A`
5. For `@Length`: Meters `@m` and the derived units millimeters `@mm` and kilometers `@km`
6. For `@Luminance`: Candela `@cd`
7. For `@Mass`: kilograms `@kg` and the derived unit grams `@g`
8. For `@Speed`: meters per second `@mPERs` and kilometers per hour `@kmPERh`
9. For `@Substance`: Mole `@mol`
10. For `@Temperature`: Kelvin `@K` and the derived unit Celsius `@C`
11. For `@Time`: seconds `@s` and the derived units minutes `@min` and hours `@h`

You may specify SI unit prefixes, using enumeration `Prefix`. The basic SI units (`@s`, `@m`, `@g`, `@A`, `@K`, `@mol`, `@cd`) take an optional `Prefix` enum as argument. For example, to use nanoseconds as unit, you could use `@s(Prefix.nano)` as a unit type. You can sometimes use a different annotation instead of a prefix; for example, `@mm` is equivalent to `@m(Prefix.milli)`.

Class `UnitsTools` contains a constant for each SI unit. To create a value of the particular unit, multiply an unqualified value with one of these constants. By using static imports, this allows very natural notation; for example, after statically importing `UnitsTools.m`, the expression `5 * m` represents five meters. As all these unit constants are public, static, and final with value one, the compiler will optimize away these multiplications.

The polymorphic annotation `@PolyUnit` enables you to write a method that takes an argument of any unit type and returns a result of that same type. For more about polymorphic qualifiers, see Section 26.2. For an example of its use, see the `@PolyUnit` Javadoc.

17.2 Extending the Units Checker

You can create new kind annotations and unit annotations that are specific to the particular needs of your project. An easy way to do this is by copying and adapting an existing annotation. (In addition, search for all uses of the annotation's name throughout the Units Checker implementation, to find other code to adapt; read on for details.)

Here is an example of a new unit annotation.

```
@Documented
@Retention(RetentionPolicy.RUNTIME)
@Target({ElementType.TYPE_USE, ElementType.PARAMETER})
@SubtypeOf({Time.class})
@UnitsMultiple(quantity=s.class, prefix=Prefix.nano)
public @interface ns {}
```

The `@SubtypeOf` meta-annotation specifies that this annotation introduces an additional unit of time. The `@UnitsMultiple` meta-annotation specifies that this annotation should be a nano multiple of the basic unit `@s`: `@ns` and `@s(Prefix.nano)` behave equivalently and interchangeably. Most annotation definitions do not have a `@UnitsMultiple` meta-annotation.

Note that all custom annotations must have the `@Target(ElementType.TYPE_USE)` meta-annotation. See section 32.5.1.

To take full advantage of the additional unit qualifier, you need to do two additional steps. (1) Provide constants that convert from unqualified types to types that use the new unit. See class `UnitsTools` for examples (you will need to suppress a checker warning in just those few locations). (2) Put the new unit in relation to existing units. Provide an implementation of the `UnitsRelations` interface as a meta-annotation to one of the units.

See demonstration `docs/examples/units-extension/` for an example extension that defines Hertz (hz) as scalar per second, and defines an implementation of `UnitsRelations` to enforce it.

17.3 What the Units Checker checks

The Units Checker ensures that unrelated types are not mixed.

All types with a particular unit annotation are disjoint from all unannotated types, from all types with a different unit annotation, and from all types with the same unit annotation but a different prefix.

Subtyping between the units and the unit kinds is taken into account, as is the `@UnitsMultiple` meta-annotation.

Multiplying a scalar with a unit type results in the same unit type.

The division of a unit type by the same unit type results in the unqualified type.

Multiplying or dividing different unit types, for which no unit relation is known to the system, will result in a `MixedUnits` type, which is separate from all other units. If you encounter a `MixedUnits` annotation in an error message, ensure that your operations are performed on correct units or refine your `UnitsRelations` implementation.

The Units Checker does *not* change units based on multiplication; for example, if variable `mass` has the type `@kg double`, then `mass * 1000` has that same type rather than the type `@g double`. (The Units Checker has no way of knowing whether you intended a conversion, or you were computing the mass of 1000 items. You need to make all conversions explicit in your code, and it's good style to minimize the number of conversions.)

17.4 Running the Units Checker

The Units Checker can be invoked by running the following commands.

- If your code uses only the SI units that are provided by the framework, simply invoke the checker:

```
javac -processor org.checkerframework.checker.units.UnitsChecker MyFile.java ...
```

- If you define your own units, provide the fully-qualified class names of the annotations through the `-Aunits` option, using a comma-no-space-separated notation:

```
javac -classpath /full/path/to/myProject/bin:/full/path/to/myLibrary/bin \  
-processor org.checkerframework.checker.units.UnitsChecker \  
-Aunits=myPackage.qual.MyUnit,myPackage.qual.MyOtherUnit MyFile.java ...
```

The annotations listed in `-Aunits` must be accessible to the compiler during compilation in the classpath. In other words, they must already be compiled (and, typically, be on the `javac` classpath) before you run the Units Checker with `javac`. It is not sufficient to supply their source files on the command line.

- You can also provide the fully-qualified paths to a set of directories that contain units qualifiers through the `-AunitsDirs` option, using a colon-no-space-separated notation. For example:

```
javac -classpath /full/path/to/myProject/bin:/full/path/to/myLibrary/bin \  
-processor org.checkerframework.checker.units.UnitsChecker \  
-AunitsDirs=/full/path/to/myProject/bin:/full/path/to/myLibrary/bin MyFile.java ...
```

Note that in these two examples, the compiled class file of the `myPackage.qual.MyUnit` and `myPackage.qual.MyOtherUnit` annotations must exist in either the `myProject/bin` directory or the `myLibrary/bin` directory. The following placement of the class files will work with the above commands:

```
.../myProject/bin/myPackage/qual/MyUnit.class  
.../myProject/bin/myPackage/qual/MyOtherUnit.class
```

The two options can be used at the same time to provide groups of annotations from directories, and individually named annotations.

Also, see the example project in the `docs/examples/units-extension` directory.

17.5 Suppressing warnings

One example of when you need to suppress warnings is when you initialize a variable with a unit type by a literal value. To remove this warning message, it is best to introduce a constant that represents the unit and to add a `@SuppressWarnings` annotation to that constant. For examples, see class `UnitsTools`.

17.6 References

Chapter 18

Signedness Checker

The Signedness Checker guarantees that signed and unsigned integral values are not mixed together in a computation. In addition, it prohibits meaningless operations, such as division on an unsigned value.

Recall that a computer represents a number as a sequence of bits. Signedness indicates how to interpret the most significant bit. For example, the bits `10000010` ordinarily represent the value `-126`, but when interpreted as unsigned, those bits represent the value `130`. The bits `01111110` represent the value `126` in signed and in unsigned interpretation. The range of signed byte values is `-128` to `127`. The range of unsigned byte values is `0` to `255`.

Signedness is only applicable to integral types: `byte`, `char`, `short`, `int`, and `long`. Floating-point types (`float` and `double`) do not have operations that interpret the bits as unsigned.

Signedness is primarily about how the bits of the representation are interpreted, not about the values that it can represent. An unsigned value is always positive, but just because a variable's value is positive does not mean that it should be marked as `@Unsigned`. If variable `v` will be compared to a signed value, or used in arithmetic operations with a signed value, then `v` should have signed type. To indicate the range of possible values for a variable, use the `@NonNegative` annotation of the Index Checker (see Chapter 8, page 70) or the `@IntRange` annotation of the Constant Value Checker (see Chapter 21, page 127).

18.1 Annotations

The Signedness Checker uses type annotations to indicate the signedness that the programmer intends an expression to have.

These are the qualifiers in the signedness type system:

`@Unsigned` indicates that the programmer intends the value to be interpreted as unsigned. That is, if the most significant bit in the bitwise representation is set, then the bits should be interpreted as a large positive value.

Figure 18.1: The type qualifier hierarchy of the signedness annotations. Qualifiers in gray are used internally by the type system but should never be written by a programmer.

@Signed indicates that the programmer intends the value to be interpreted as signed. That is, if the most significant bit in the bitwise representation is set, then the bits should be interpreted as a negative value. This is the default annotation.

@SignedPositive indicates that a value is known at compile time to be in the positive signed range, so it has the same interpretation as signed or unsigned and may be used with either interpretation. Programmers should usually write **@Signed** or **@Unsigned** instead.

@SignednessGlb indicates that a value may be interpreted as unsigned or signed. It covers the same cases as **@SignedPositive**, plus manifest literals, to prevent the programmer from having to annotate them all explicitly. This annotation should almost never be written by the programmer.

@PolySigned indicates qualifier polymorphism. For a description of qualifier polymorphism, see Section 26.2.

@UnknownSignedness indicates that a value's type is not relevant or known to this checker. This annotation is used internally, and should not be written by the programmer.

@SignednessBottom indicates that the value is `null`. This annotation is used internally, and should not be written by the programmer.

18.1.1 Default qualifiers

The only type qualifier that the programmer should need to write is **@Unsigned**. When a programmer leaves an expression unannotated, the Signedness Checker treats it in one of the following ways:

- All byte, short, int, and long literals default to **@SignednessGlb**.
- All byte, short, int, and long variables default to **@Signed**.
- All other expressions default to **@UnknownSignedness**.

18.2 Prohibited operations

The Signedness Checker prohibits the following uses of operators:

- Division (/) or modulus (%) with an **@Unsigned** operand.
- Signed right shift (>>) with an **@Unsigned** left operand.
- Unsigned right shift (>>>) with a **@Signed** left operand.
- Greater/less than (or equal) comparators (<, <=, >, >=) with an **@Unsigned** operand.
- Any other binary operator with one **@Unsigned** operand and one **@Signed** operand, with the exception of left shift (<<).

Like every type-checker built with the Checker Framework, the Signedness Checker ensures that assignments and pseudo-assignments have consistent types. For example, it is not permitted to assign a **@Signed** expression to an **@Unsigned** variable or vice versa.

18.3 Rationale

The Signedness Checker prevents misuse of unsigned values in Java code. Most Java operations interpret operands as signed. If applied to unsigned values, those operations would produce unexpected, incorrect results.

Consider the following Java code:

```
public class SignednessManualExample {  
  
    int s1 = -2;  
    int s2 = -1;  
  
    @Unsigned int u1 = 2147483646; // unsigned: 2^32 - 2, signed: -2
```

```

@Unsigned int u2 = 2147483647; // unsigned: 2^32 - 1, signed: -1

void m() {
    int w = s1 / s2; // OK: result is 2, which is correct for -2 / -1
    int x = u1 / u2; // ERROR: result is 2, which is incorrect for (2^32 - 2) / (2^32 - 1)
}

int s3 = -1;
int s4 = 5;

@Unsigned int u3 = 2147483647; // unsigned: 2^32 - 1, signed: -1
@Unsigned int u4 = 5;

void m2() {
    int y = s3 % s4; // OK: result is -1, which is correct for -1 % 5
    int z = u3 % u4; // ERROR: result is -1, which is incorrect for (2^32 - 1) % 5 = 2
}
}

```

These examples illustrate why division and modulus with an unsigned operand are illegal. Other uses of operators are prohibited for similar reasons.

18.4 Utility routines for manipulating unsigned values

Class `SignednessUtil` provides static utility methods for working with unsigned values. They are properly annotated with `@Unsigned` where appropriate, so using them may reduce the number of annotations that you need to write.

Class `SignednessUtilExtra` contains more utility methods that reference packages not included in Android. This class is not included in `checker-qual.jar`, so you may want to copy the methods to your code.

18.5 Local type refinement

Local type refinement/inference (Section 27.7) may be surprising for the `Signedness` type system. Ordinarily, an expression with unsigned type may not participate in a division, as shown in Sections 18.2 and 18.3. However, if a constant is assigned to a variable that was declared with `@Unsigned` type, then—just like the constant—the variable may be treated as either signed or unsigned. For example, it can participate in division. Since the result of the division is signed, you cannot accidentally assign the division result to an `@Unsigned` variable.

```

void useLocalVariables() {

    int s1 = -2;
    int s2 = -1;

    @Unsigned int u1 = 2147483646; // unsigned: 2^32 - 2, signed: -2
    @Unsigned int u2 = 2147483647; // unsigned: 2^32 - 1, signed: -1

    int w = s1 / s2; // OK: result is 2, which is correct for -2 / -1
    int x = u1 / u2; // OK: computation over constants, interpreted as signed; result is signed
}

```

Chapter 19

Aliasing Checker

The Aliasing Checker identifies expressions that definitely have no aliases.

Two expressions are aliased when they have the same non-primitive value; that is, they are references to the identical Java object in the heap. Another way of saying this is that two expressions, *exprA* and *exprB*, are aliases of each other when *exprA==exprB* at the same program point.

Assigning to a variable or field typically creates an alias. For example, after the statement `a = b;`, the variables `a` and `b` are aliased.

Knowing that an expression is not aliased permits more accurate reasoning about how side effects modify the expression's value.

To run the Aliasing Checker, supply the `-processor org.checkerframework.common.aliasing.AliasingChecker` command-line option to `javac`. However, a user rarely runs the Aliasing Checker directly. This type system is mainly intended to be used together with other type systems. For example, the SPARTA information flow type-checker (Section 25.10) uses the Aliasing Checker to improve its type refinement — if an expression has no aliases, a more refined type can often be inferred, otherwise the type-checker makes conservative assumptions.

19.1 Aliasing annotations

There are two possible types for an expression:

@MaybeAliased is the type of an expression that might have an alias. This is the default, so every unannotated type is `@MaybeAliased`. (This includes the type of `null`.)

@Unique is the type of an expression that has no aliases.

The `@Unique` annotation is only allowed at local variables, method parameters, constructor results, and method returns. A constructor's result should be annotated with `@Unique` only if the constructor's body does not create an alias to the constructed object.

There are also two annotations, which are currently trusted instead of verified, that can be used on formal parameters (including the receiver parameter, `this`):

Figure 19.1: Type hierarchy for the Aliasing type system. These qualifiers are applicable to any reference (non-primitive) type.

@NonLeaked identifies a formal parameter that is not leaked nor returned by the method body. For example, the formal parameter of the String copy constructor, `String(String s)`, is **@NonLeaked** because the body of the method only makes a copy of the parameter.

@LeakedToResult is used when the parameter may be returned, but it is not otherwise leaked. For example, the receiver parameter of `StringBuffer.append(StringBuffer this, String s)` is **@LeakedToResult**, because the method returns the updated receiver.

19.2 Leaking contexts

This section lists the expressions that create aliases. These are also called “leaking contexts”.

Assignments After an assignment, the left-hand side and the right-hand side are typically aliased. (The only counterexample is when the right-hand side is a fresh expression; see Section 19.4.)

```
@Unique Object u = ...;
Object o = u;           // (not.unique) type-checking error!
```

If this example type-checked, then `u` and `o` would be aliased. For this example to type-check, either the **@Unique** annotation on the type of `u`, or the `o = u;` assignment, must be removed.

Method calls and returns (pseudo-assignments) Passing an argument to a method is a “pseudo-assignment” because it effectively assigns the argument to the formal parameter. Return statements are also pseudo-assignments. As with assignments, the left-hand side and right-hand side of pseudo-assignments are typically aliased.

Here is an example for argument-passing:

```
void mightDoAnything(Object o) { ... }
```

```
@Unique Object u = ...;
mightDoAnything(u); // type-checking error, because the callee may create an alias of the passed argument
```

Passing a non-aliased reference to a method does not necessarily create an alias. However, the body of the method might create an alias or leak the reference. Thus, the Aliasing Checker always treats a method call as creating aliases for each argument unless the corresponding formal parameter is marked as **@NonLeaked** or **@LeakedToResult**.

Here is an example for a return statement:

```
Object id(@Unique Object p) {
    return p; // (not.unique) type-checking error!
}
```

If this code type-checked, then it would be possible for clients to write code like this:

```
@Unique Object u = ...;
Object o = id(u);
```

after which there is an alias to `u` even though it is declared as **@Unique**.

However, it is permitted to write

```
Object id(@LeakedToResult Object p) {
    return p;
}
```

after which the following code type-checks:

```
@Unique Object u = ...;
id(u);           // method call result is not used
Object o1 = ...;
Object o2 = id(o1); // argument is not @Unique
```

Throws A thrown exception can be captured by a catch block, which creates an alias of the thrown exception.

```

void aliasInCatchBlock() {
    @Unique Exception uex = new Exception();
    try {
        throw uex;    // (not.unique) type-checking error!
    } catch (Exception ex) {
        // uex and ex refer to the same object here.
    }
}

```

Array initializers Array initializers assign the elements in the initializers to corresponding indexes in the array, therefore expressions in an array initializer are leaked.

```

void aliasInArrayInitializer() {
    @Unique Object o = new Object();
    Object[] ar = new Object[] { o }; // (not.unique) type-checking error!
    // The expressions o and ar[0] are now aliased.
}

```

19.3 Restrictions on where @Unique may be written

The @Unique qualifier may not be written on locations such as fields, array elements, and type parameters.

As an example of why @Unique may not be written on a field's type, consider the following code:

```

class MyClass {
    @Unique Object field;
    void makesAlias() {
        MyClass myClass2 = this;
        // this.field is now an alias of myClass2.field
    }
}

```

That code must not type-check, because `field` is declared as @Unique but has an alias. The Aliasing Checker solves the problem by forbidding the @Unique qualifier on subcomponents of a structure, such as fields. Other solutions might be possible; they would be more complicated but would permit more code to type-check.

@Unique may not be written on a type parameter for similar reasons. The assignment

```

List<@Unique Object> l1 = ...;
List<@Unique Object> l2 = l1;

```

must be forbidden because it would alias `l1.get(0)` with `l2.get(0)` even though both have type @Unique. The Aliasing Checker forbids this code by rejecting the type `List<@Unique Object>`.

19.4 Aliasing type refinement

Type refinement enables a type checker to treat an expression as a subtype of its declared type. For example, even if you declare a local variable as @MaybeAliased (or don't write anything, since @MaybeAliased is the default), sometimes the Aliasing Checker can determine that it is actually @Unique. For more details, see Section 27.7.

The Aliasing Checker treats type refinement in the usual way, except that at (pseudo-)assignments the right-hand-side (RHS) may lose its type refinement, before the left-hand-side (LHS) is type-refined. The RHS always loses its type refinement (it is widened to @MaybeAliased, and its declared type must have been @MaybeAliased) except in the following cases:

```

// Annotations on the StringBuffer class, used in the examples below.
// class StringBuffer {
//   @Unique StringBuffer();
//   StringBuffer append(@LeakedToResult StringBuffer this, @NonLeaked String s);
// }

void foo() {
    StringBuffer sb = new StringBuffer();    // sb is refined to @Unique.

    StringBuffer sb2 = sb;                  // sb loses its refinement.
    // Both sb and sb2 have aliases and because of that have type @MaybeAliased.
}

void bar() {
    StringBuffer sb = new StringBuffer();    // sb is refined to @Unique.

    sb.append("someString");
    // sb stays @Unique, as no aliases are created.

    StringBuffer sb2 = sb.append("someString");
    // sb is leaked and becomes @MaybeAliased.

    // Both sb and sb2 have aliases and because of that have type @MaybeAliased.
}

```

Figure 19.2: Example of the Aliasing Checker’s type refinement rules.

- The RHS is a fresh expression — an expression that returns a different value each time it is evaluated. In practice, this is only method/constructor calls with @Unique return type. A variable/field is not fresh because it can return the same value when evaluated twice.
- The LHS is a @NonLeaked formal parameter and the RHS is an argument in a method call or constructor invocation.
- The LHS is a @LeakedToResult formal parameter, the RHS is an argument in a method call or constructor invocation, and the method’s return value is discarded — that is, the method call or constructor invocation is written syntactically as a statement rather than as a part of a larger expression or statement.

A consequence of the above rules is that most method calls are treated conservatively. If a variable with declared type @MaybeAliased has been refined to @Unique and is used as an argument of a method call, it usually loses its @Unique refined type.

Figure 19.2 gives an example of the Aliasing Checker’s type refinement rules.

Chapter 20

Purity Checker

The Purity Checker identifies methods that have no side effects, that return the same value each time they are called on the same argument, or both.

Purity analysis aids type refinement (Section 27.7).

All checkers utilize purity annotations on called methods. You do not need to run the Purity Checker directly. However you may run just the Purity Checker by supplying the following command-line options to `javac`: `-processor org.checkerframework.util.PurityChecker`.

20.1 Purity annotations

`@SideEffectFree` indicates that the method has no externally-visible side effects.

`@Deterministic` indicates that if the method is called multiple times with identical arguments, then it returns the identical result according to `==` (not just according to `equals()`).

`@Pure` indicates that the method is both `@SideEffectFree` and `@Deterministic`.

If you supply the command-line option `-AsuggestPureMethods`, then the Checker Framework will suggest methods that can be marked as `@SideEffectFree`, `@Deterministic`, or `@Pure`.

20.2 Purity annotations are trusted

Currently, purity annotations are trusted. Purity annotations on called methods affect type-checking of client code. However, you can make a mistake by writing `@SideEffectFree` on the declaration of a method that is not actually side-effect-free or by writing `@Deterministic` on the declaration of a method that is not actually deterministic.

To enable checking of the annotations, supply the command-line option `-AcheckPurityAnnotations`. It is not enabled by default because of a high false positive rate. In the future, after a new purity-checking analysis is implemented, the Checker Framework will default to checking purity annotations.

20.3 Overriding methods must respect specifications in superclasses

If a method in a superclass has a purity annotation, then every overriding definition must also have that purity annotation (or a stronger one).

Here is an example error if this requirement is violated:

```
MyClass.java:1465: error: int hashCode() in MyClass cannot override int hashCode(Object this) in java.lang.Object;
attempting to use an incompatible purity declaration
    public int hashCode() {
           ^
```

```
found : []
required: [SIDE_EFFECT_FREE, DETERMINISTIC]
```

The reason for the error is that the `Object` class is annotated as:

```
class Object {
    ...
    @Pure int hashCode() { ... }
}
```

(where `@Pure` means both `@SideEffectFree` and `@Deterministic`). Every overriding definition, including those in your program, must use be at least as strong a specification. For `hashCode`, every overriding definition must be annotated as `@Pure`.

You can fix the definition by adding `@Pure` to your method definition. Alternately, you can suppress the warning. You can suppress each such warning individually using `@SuppressWarnings("purity.invalid.overriding")`, or you can use the `-AsuppressWarnings=purity.invalid.overriding` command-line argument to suppress all such warnings. In the future, the Checker Framework will support inheriting annotations from superclass definitions.

20.4 Suppressing warnings

The command-line options `-AassumeSideEffectFree`, `-AassumeDeterministic`, `-AassumePure` make the Checker Framework unsoundly assume that *every* called method is side-effect-free, is deterministic, or is both, respectively. This can make flow-sensitive type refinement much more effective, since method calls will not cause the analysis to discard information that it has learned. However, this option can mask real errors. It is most appropriate when you are starting out annotating a project, or if you are using the Checker Framework to find some bugs but not to give a guarantee that no more errors exist of the given type.

Chapter 21

Constant Value Checker

The Constant Value Checker is a constant propagation analysis: for each variable, it determines whether that variable's value can be known at compile time.

There are two ways to run the Constant Value Checker.

- Typically, it is automatically run by another type checker.
- Alternately, you can run just the Constant Value Checker, by supplying the following command-line options to `javac`: `-processor org.checkerframework.common.value.ValueChecker -Astubs=statically-executable.astub`

21.1 Annotations

The Constant Value Checker uses type annotations to indicate the value of an expression (Section 21.1.1), and it uses method annotations to indicate methods that the Constant Value Checker can execute at compile time (Section 21.2.2).

21.1.1 Type Annotations

Typically, the programmer does not write any type annotations. Rather, the type annotations are inferred by the Constant Value Checker. The programmer is also permitted to write type annotations. This is only necessary in locations where the Constant Value Checker does not infer annotations: on fields and method signatures.

The main type annotations are `@BoolVal`, `@IntVal`, `@IntRange`, `@DoubleVal`, and `@StringVal`. Additional type annotations for arrays and strings are `@ArrayLen`, `@ArrayLenRange`, and `@MinLen`. A polymorphic qualifier (`@PolyValue`) is also supported (see Section 26.2). In addition, there are separate checkers for `@ClassVal` and `@MethodVal` annotations (see Section 23.2).

Each `*Val` type annotation takes as an argument a set of values, and its meaning is that at run time, the expression evaluates to one of the values. For example, an expression of type `@StringVal("a", "b")` evaluates to one of the values "a", "b", or null. The set is limited to 10 entries; if a variable could be more than 10 different values, the Constant Value Checker gives up and its type becomes `@IntRange` for integral types, `@ArrayLenRange` for array types, `@ArrayLen` or `@ArrayLenRange` for `String`, and `@UnknownVal` for all other types. The `@ArrayLen` annotation means that at run time, the expression evaluates to an array or a string whose length is one of the annotation's arguments.

In the case of too many strings in `@StringVal`, the values are forgotten and just the lengths are used in `@ArrayLen`. If this would result in too many lengths, only the minimum and maximum lengths are used in `@ArrayLenRange`, giving a range of possible lengths of the string.

The `@StringVal` annotation may be applied to a char array. Although byte arrays are often converted to/from strings, the `@StringVal` annotation may not be applied to them. This is because the conversion depends on the platform's character set.

`@IntRange` takes two arguments — a lower bound and an upper bound. Its meaning is that at run time, the expression evaluates to a value between the bounds (inclusive). For example, an expression of type `@IntRange(from=0, to=255)` evaluates to 0, 1, 2, ..., 254, or 255. An `@IntVal` and `@IntRange` annotation that represent the same set of values

Figure 21.1: At the top, the type qualifier hierarchy of the Constant Value Checker annotations. The first four qualifiers are applicable to primitives and their wrappers; the next to `Strings`, and the final two to arrays. Qualifiers in gray are used internally by the type system but should never be written by a programmer. At the bottom are examples of additional subtyping relationships that depend on the annotations' arguments.

```
public void flowSensitivityExample(boolean b) {
    int i = 1;    // i has type: @IntVal({1}) int
    if (b) {
        i = 2;    // i now has type: @IntVal({2}) int
    }

    // i now has type: @IntVal({1,2}) int
    i = i + 1;    // i now has type: @IntVal({2,3}) int
}
```

Figure 21.2: The Constant Value Checker infers different types for a variable on different lines of the program.

are semantically identical and interchangeable: they have exactly the same meaning, and using either one has the same effect. `@ArrayLenRange` has the same relationship to `@ArrayLen` that `@IntRange` has to `@IntVal`. The `@MinLen` annotation is an alias for `@ArrayLenRange` (meaning that every `@MinLen` annotation is automatically converted to an `@ArrayLenRange` annotation) that only takes one argument, which is the lower bound of the range. The upper bound of the range is the maximum integer value.

Figure 21.1 shows the subtyping relationship among the type annotations. For two annotations of the same type, subtypes have a smaller set of possible values, as also shown in the figure. Because `int` can be casted to `double`, an `@IntVal` annotation is a subtype of a `@DoubleVal` annotation with the same values.

Figure 21.2 illustrates how the Constant Value Checker infers type annotations (using flow-sensitive type qualifier refinement, Section 27.7).

21.2 Other constant value annotations

The Checker Framework's constant value annotations are similar to annotations used elsewhere.

If your code is already annotated with a different constant value or range annotation, the Checker Framework can

`android.support.annotation.IntRange` ⇒ `org.checkerframework.checker.common.value.qual.IntRange`

Figure 21.3: Correspondence between other constant value and range annotations and the Checker Framework’s annotations.

```
@StaticallyExecutable @Pure
public int myAdd(int a, int b) {
    return a + b;
}

public void bar() {
    int a = 5;           // a has type: @IntVal({5}) int
    int b = 4;           // b has type: @IntVal({4}) int
    int c = myAdd(a, b); // c has type: @IntVal({9}) int
}
```

Figure 21.4: The `@StaticallyExecutable` annotation enables constant propagation through method calls.

type-check your code. It treats annotations from other tools as if you had written the corresponding annotation from the Constant Value Checker, as described in Figure 21.3. If the other annotation is a declaration annotation, it may be moved; see Section 29.1.1.

21.2.1 Compile-time execution of expressions

Whenever all the operands of an expression are compile-time constants (that is, their types have constant-value type annotations), the Constant Value Checker attempts to execute the expression. This is independent of any optimizations performed by the compiler and does not affect the code that is generated.

The Constant Value Checker statically executes operators that do not throw exceptions (e.g., +, -, <<, !=).

21.2.2 `@StaticallyExecutable` methods and the classpath

The Constant Value Checker statically executes methods annotated with `@StaticallyExecutable`, *if the method has already been compiled and is on the classpath*.

A `@StaticallyExecutable` method must be `@Pure` (side-effect-free and deterministic).

Additionally, a `@StaticallyExecutable` method and any method it calls must be on the classpath for the compiler, because they are reflectively called at compile-time to perform the constant value analysis. To use `@StaticallyExecutable` on methods in your own code, you should first compile the code without the Constant Value Checker and then add the location of the resulting `.class` files to the classpath. For example, the command-line arguments to the Checker Framework might include:

```
-processor org.checkerframework.common.value.ValueChecker
-Astubs=statically-executable.astub
-classpath $CLASSPATH:MY_PROJECT/build/
```

21.3 Warnings

If the option `-AreportEvalWarns` options is used, the Constant Value Checker issues a warning if it cannot load and run, at compile time, a method marked as `@StaticallyExecutable`. If it issues such a warning, then the return value of the method will be `@UnknownVal` instead of being able to be resolved to a specific value annotation. Some examples of these:

```

...
if (i > 5) {
    // i now has type: @IntRange(from=5, to=Integer.MAX_VALUE)
    i = i + 1;
    // If i started out as Integer.MAX_VALUE, then i is now Integer.MIN_VALUE.
    // i's type is now @IntRange(from=Integer.MIN_VALUE, to=Integer.MAX_VALUE).
    // When ignoring overflow, i's type is now @IntRange(from=6, to=Integer.MAX_VALUE).
}

```

Figure 21.5: With the `-AignoreRangeOverflow` command-line option, the Constant Value Checker ignores overflow for range types, which gives smaller ranges to range types.

- `[class.find.failed]` Failed to find class named `Test`.
The checker could not find the class specified for resolving a `@StaticallyExecutable` method. Typically this is caused by not providing the path of a class-file needed to the classpath.
- `[method.find.failed]` Failed to find a method named `foo` with argument types `[@IntVal(3) int]`.
The checker could not find the method `foo(int)` specified for resolving a `@StaticallyExecutable` method, but could find the class. This is usually due to providing an outdated version of the class-file that does not contain the method that was annotated as `@StaticallyExecutable`.
- `[method.evaluation.exception]` Failed to evaluate method `public static int Test.foo(int)` because it threw an exception: `java.lang.ArithmeticException: / by zero`.
An exception was thrown when trying to statically execute the method. In this case it was a divide-by-zero exception. If the arguments to the method each only had one value in their annotations then this exception will always occur when the program is actually run as well. If there are multiple possible values then the exception might not be thrown on every execution, depending on the run-time values.

There are some other situations in which the Constant Value Checker produces a warning message:

- `[too.many.values.given]` The maximum number of arguments permitted is 10.
The Constant Value Checker only tracks up to 10 possible values for an expression. If you write an annotation with more values than will be tracked, the annotation is replaced with `@IntRange`, `@ArrayLen`, `@ArrayLenRange`, or `@UnknownVal`.

21.4 Unsoundly ignoring overflow

The Constant Value Checker takes Java's overflow rules into account when computing the possible values of expressions. The `-AignoreRangeOverflow` command-line option makes it ignore the possibility of overflow for range annotations `@IntRange` and `@ArrayLenRange`. Figure 21.5 gives an example of behavior with and without the `-AignoreRangeOverflow` command-line option.

As with any unsound behavior in the Checker Framework, this option reduces the number of warnings and errors produced, and may reduce the number of `@IntRange` qualifiers that you need to write in the source code. However, it is possible that at run time, an expression might evaluate to a value that is not in its `@IntRange` qualifier. You should either accept that possibility, or verify the lack of overflow using some other tool or manual analysis.

21.5 Strings can be null in concatenations

By default, the Constant Value Checker is sound with respect to string concatenation and nullness. It assumes that, in a string concatenation, every non-primitive argument might be null, except for `String` literals and compile-time constants. It ignores `Nullness` Checker annotations. (This behavior is conservative but sound.)

Consider a variable declared as `@StringVal("a", "b") String x;` At run time, `x` evaluates to one of the values "a", "b", or null. Therefore, the type of "`x + "c"`" is `@StringVal("ac", "bc", "nullc") String`.

The `-AnonNullStringsConcatenation` command-line option makes the Constant Value Checker unsoundly assume that no arguments in a string concatenation are null. With the command-line argument, the type of "`x + "c"`" is `@StringVal("ac", "bc") String`.

Chapter 22

Returns Receiver Checker

The Returns Receiver Checker enables documenting and checking that a method returns its receiver (i.e., the `this` parameter).

There are two ways to run the Returns Receiver Checker.

- Typically, it is automatically run by another checker.
- Alternately, you can run just the Returns Receiver Checker, by supplying the following command-line options to `javac`: `-processor org.checkerframework.common.returnsreceiver.ReturnsReceiverChecker`

22.1 Annotations

The qualifier `@This` on the return type of a method indicates that the method returns its receiver. Methods that return their receiver are common in so-called “fluent” APIs. Here is an example:

```
class MyBuilder {
    @This MyBuilder setName(String name) {
        this.name = name;
        return this;
    }
}
```

An `@This` annotation can only be written on a return type, a receiver type, or in a downcast.

As is standard, the Returns Receiver Checker has a top qualifier, `@UnknownThis`, and a bottom qualifier, `@BottomThis`. Programmers rarely need to write these annotations.

Here are additional details. `@This` is a polymorphic qualifier rather than a regular type qualifier ((see Section 26.2). Conceptually, a receiver type always has an `@This` qualifier. When a method return type also has an `@This` qualifier, the presence of the polymorphic annotation on both the method’s return and receiver type forces their type qualifiers to be *equal*. Hence, the method will only pass the type checker if it returns its receiver argument, achieving the desired checking.

22.2 AutoValue and Lombok Support

The AutoValue and Lombok projects both support automatic generation of builder classes, which enable flexible object construction. For code using these two frameworks, the Returns Receiver Checker automatically adds `@This` annotations to setter methods in builder classes. All the `@This` annotations in Figures 22.1 and 22.2 are automatically added by the Returns Receiver Checker.

```

@AutoValue
abstract class Animal {
    abstract String name();
    abstract int numberOfLegs();
    static Builder builder() {
        return new AutoValue_Animal.Builder();
    }
}
@AutoValue.Builder
abstract static class Builder {
    abstract Builder setName(String value); // @This is automatically added here
    abstract Builder setNumberOfLegs(int value); // @This is automatically added here
    abstract Animal build();
}
}

```

Figure 22.1: User-written code that uses the `@AutoValue.Builder` annotation. Given this code, (1) `AutoValue` automatically generates a concrete subclass of `Animal.Builder`, see Figure 22.2, and (2) the Returns Receiver Checker automatically adds `@This` annotations on setters in both user-written and automatically-generated code.

```

class AutoValue_Animal {
    static final class Builder extends Animal.Builder {
        private String name;
        private Integer numberOfLegs;
        @This Animal.Builder setName(String name) {
            this.name = name;
            return this;
        }
        @This Animal.Builder setNumberOfLegs(int numberOfLegs) {
            this.numberOfLegs = numberOfLegs;
            return this;
        }
        @Override
        Animal build() {
            return new AutoValue_Animal(this.name, this.numberOfLegs);
        }
    }
}

```

Figure 22.2: Code generated by `AutoValue` for the example of Figure 22.1, including the `@This` annotations added by the Returns Receiver Checker.

Chapter 23

Reflection resolution

A call to `Method.invoke` might reflectively invoke any method. That method might place requirements on its formal parameters, and it might return any value. To reflect these facts, the annotated JDK contains conservative annotations for `Method.invoke`. These conservative library annotations often cause a checker to issue false positive warnings when type-checking code that uses reflection.

If you supply the `-AresolveReflection` command-line option, the Checker Framework attempts to resolve reflection. At each call to `Method.invoke` or `Constructor.newInstance`, the Checker Framework first soundly estimates which methods might be invoked at run time. When type-checking the call, the Checker Framework uses the library annotations for the possibly-invoked methods, rather than the imprecise one for `Method.invoke`.

If the estimate of invoked methods is small, the checker issues fewer false positive warnings. If the estimate of invoked methods is large, these types may be no better than the conservative library annotations.

Reflection resolution is disabled by default, because it increases the time to type-check a program. You should enable reflection resolution with the `-AresolveReflection` command-line option if, for some call site of `Method.invoke` or `Constructor.newInstance` in your program:

1. the conservative library annotations on `Method.invoke` or `Constructor.newInstance` cause false positive warnings,
2. the set of possibly-invoked methods or constructors can be known at compile time, and
3. the reflectively invoked methods/constructors are on the class path at compile time.

Reflection resolution does not change your source code or generated code. In particular, it does not replace the `Method.invoke` or `Constructor.newInstance` calls.

The command-line option `-AresolveReflection=debug` outputs verbose information about the reflection resolution process, which may be useful for debugging.

Section 23.1 gives an example of reflection resolution. Then, Section 23.2 describes the `MethodVal` and `ClassVal` Checkers, which reflection resolution uses internally.

23.1 Reflection resolution example

Consider the following example, in which the Nullness Checker employs reflection resolution to avoid issuing a false positive warning.

```
public class LocationInfo {
    @NonNull Location getLocation() { ... }
}

public class Example {
    LocationInfo privateLocation = ... ;
}
```

```

String getCurrentCity() throws Exception {
    Method getLocationObj = LocationInfo.class.getMethod("getLocation");
    Location currentLocation = (Location) getLocationObj.invoke(privateLocation);
    return currentLocation.nameOfCity();
}
}

```

When reflection resolution is not enabled, the Nullness Checker uses conservative annotations on the `Method.invoke` method signature:

```
@Nullable Object invoke(@NonNull Object recv, @NonNull Object ... args)
```

This causes the Nullness Checker to issue the following warning even though `currentLocation` cannot be null.

```

error: [dereference.of.nullable] dereference of possibly-null reference currentLocation
    return currentLocation.nameOfCity();
           ^
1 error

```

When reflection resolution is enabled, the `MethodVal` Checker infers that the `@MethodVal` annotation for `getLocationObj` is:

```
@MethodVal(className="LocationInfo", methodName="getLocation", params=0)
```

Based on this `@MethodVal` annotation, the reflection resolver determines that the reflective method call represents a call to `getLocation` in class `LocationInfo`. The reflection resolver uses this information to provide the following precise procedure summary to the Nullness Checker, for this call site only:

```
@NonNull Object invoke(@NonNull Object recv, @Nullable Object ... args)
```

Using this more precise signature, the Nullness Checker does not issue the false positive warning shown above.

23.2 MethodVal and ClassVal Checkers

The implementation of reflection resolution internally uses the `ClassVal` Checker (Section 23.2.1) and the `MethodVal` Checker (Section 23.2.2). They are similar to the Constant Value Checker (Section 21) in that their annotations estimate the run-time value of an expression.

In some cases, you may need to write annotations such as `@ClassVal`, `@MethodVal`, `@StringVal`, and `@ArrayLen` to aid in reflection resolution. Often, though, these annotations can be inferred (Section 23.2.3).

23.2.1 ClassVal Checker

The `ClassVal` Checker defines the following annotations:

@ClassVal(String[] value) If an expression has `@ClassVal` type with a single argument, then its exact run-time value is known at compile time. For example, `@ClassVal("java.util.HashMap")` indicates that the `Class` object represents the `java.util.HashMap` class.

If multiple arguments are given, then the expression's run-time value is known to be in that set.

The arguments are binary names (JLS §13.1).

@ClassBound(String[] value) If an expression has `@ClassBound` type, then its run-time value is known to be upper-bounded by that type. For example, `@ClassBound("java.util.HashMap")` indicates that the `Class` object represents `java.util.HashMap` or a subclass of it.

If multiple arguments are given, then the run-time value is equal to or a subclass of some class in that set.

The arguments are binary names (JLS §13.1).

@UnknownClass Indicates that there is no compile-time information about the run-time value of the class — or that the Java type is not `Class`. This is the default qualifier, and it may not be written in source code.

@ClassValBottom Type given to the null literal. It may not be written in source code.

Figure 23.1: Partial type hierarchy for the ClassVal type system. The type qualifiers in gray (@UnknownClass and @ClassValBottom) should never be written in source code; they are used internally by the type system.

Subtyping rules

Figure 23.1 shows part of the type hierarchy of the ClassVal type system. @ClassVal(A) is a subtype of @ClassVal(B) if A is a subset of B. @ClassBound(A) is a subtype of @ClassBound(B) if A is a subset of B. @ClassVal(A) is a subtype of @ClassBound(B) if A is a subset of B.

23.2.2 MethodVal Checker

The MethodVal Checker defines the following annotations:

@MethodVal(String[] className, String[] methodName, int[] params) Indicates that an expression of type Method or Constructor has a run-time value in a given set. If the set has size n , then each of @MethodVal's arguments is an array of size n , and the i th method in the set is represented by { className[i], methodName[i], params[i] }. For a constructor, the method name is "<init>".

Consider the following example:

```
@MethodVal(className={"java.util.HashMap", "java.util.HashMap"},
            methodName={"containsKey", "containsValue"},
            params={1, 1})
```

This @MethodVal annotation indicates that the Method is either HashMap.containsKey with 1 formal parameter or HashMap.containsValue with 1 formal parameter.

The @MethodVal type qualifier indicates the number of parameters that the method takes, but not their type. This means that the Checker Framework's reflection resolution cannot distinguish among overloaded methods.

@UnknownMethod Indicates that there is no compile-time information about the run-time value of the method — or that the Java type is not Method or Constructor. This is the default qualifier, and it may not be written in source code.

@MethodValBottom Type given to the null literal. It may not be written in source code.

Subtyping rules

Figure 23.2 shows part of the type hierarchy of the MethodVal type system. @MethodVal(className=CA, methodName=MA, params=PA) is a subtype of @MethodVal(className=CB, methodName=MB, params=PB) if

$$\forall \text{index } i \exists \text{an index } j : CA[i] = CB[j], MA[i] = MB[j], \text{ and } PA[i] = PB[j]$$

where CA, MA, and PA are lists of equal size and CB, MB, and PB are lists of equal size.

Figure 23.2: Partial type hierarchy for the MethodVal type system. The type qualifiers in gray (@UnknownMethod and @MethodValBottom) should never be written in source code; they are used internally by the type system.

$$\begin{array}{c}
 \frac{bn \text{ is the binary name of } C}{C.class : @ClassVal(bn)} \\
 \\
 \frac{s : @StringVal(v)}{Class.forName(s) : @ClassVal(v)} \\
 \\
 \frac{e : \tau \quad bn \text{ is the binary name of } \tau}{e.getClass() : @ClassBound(bn)} \\
 \\
 \frac{\begin{array}{l} (e : @ClassBound(v) \vee e : @ClassVal(v)) \\ s : @StringVal(\mu) \quad p : @ArrayLen(\pi) \end{array}}{e.getMethod(s, p) : @MethodVal(cn=v, mn=\mu, np=\pi)} \\
 \\
 \frac{e : @ClassVal(v) \quad p : @ArrayLen(\pi)}{e.getConstructor(p) : @MethodVal(cn=v, mn = "<init>", np = \pi)}
 \end{array}$$

Figure 23.3: Example inference rules for @ClassVal, @ClassBound, and @MethodVal. Additional rules exist for expressions with similar semantics but that call methods with different names or signatures.

23.2.3 MethodVal and ClassVal inference

The developer rarely has to write @ClassVal or @MethodVal annotations, because the Checker Framework infers them according to Figure 23.3. Most readers can skip this section, which explains the inference rules.

The ClassVal Checker infers the exact class name (@ClassVal) for a Class literal (C.class), and for a static method call (e.g., Class.forName(arg), ClassLoader.loadClass(arg), ...) if the argument is a statically computable expression. In contrast, it infers an upper bound (@ClassBound) for instance method calls (e.g., obj.getClass()).

The MethodVal Checker infers @MethodVal annotations for Method and Constructor types that have been created using a method call to Java's Reflection API:

- Class.getMethod(String name, Class<?>... paramTypes)
- Class.getConstructor(Class<?>... paramTypes)

Note that an exact class name is necessary to precisely resolve reflectively-invoked constructors since a constructor in a subclass does not override a constructor in its superclass. This means that the MethodVal Checker does not infer a @MethodVal annotation for Class.getConstructor if the type of that class is @ClassBound. In contrast, either an exact class name or a bound is adequate to resolve reflectively-invoked methods because of the subtyping rules for overridden methods.

Chapter 24

Subtyping Checker

The Subtyping Checker enforces only subtyping rules. It operates over annotations specified by a user on the command line. Thus, users can create a simple type-checker without writing any code beyond definitions of the type qualifier annotations.

The Subtyping Checker can accommodate all of the type system enhancements that can be declaratively specified (see Chapter 32). This includes type introduction rules via the `@QualifierForLiterals` meta-annotation, and other features such as type refinement (Section 27.7) and qualifier polymorphism (Section 26.2).

The Subtyping Checker is also useful to type system designers who wish to experiment with a checker before writing code; the Subtyping Checker demonstrates the functionality that a checker inherits from the Checker Framework.

If you need tpestate analysis, then you can extend a tpestate checker. For more details (including a definition of “tpestate”), see Chapter 25.17. See Section 34.7.1 for a simpler alternative.

For type systems that require special checks (e.g., warning about dereferences of possibly-null values), you will need to write code and extend the framework as discussed in Chapter 32.

24.1 Using the Subtyping Checker

The Subtyping Checker is used in the same way as other checkers (using the `-processor org.checkerframework.common.subtyping.SubtypingChecker` option; see Chapter 2), except that it requires an additional annotation processor argument via the standard “-A” switch. You must provide one or both of the two following command-line arguments:

- Provide the fully-qualified class name(s) of the annotation(s) in the custom type system through the `-Aquals` option, using a comma-no-space-separated notation:

```
javac -classpath /full/path/to/myProject/bin:/full/path/to/myLibrary/bin \  
      -processor org.checkerframework.common.subtyping.SubtypingChecker \  
      -Aquals=myPackage.qual.MyQual,myPackage.qual.OtherQual MyFile.java ...
```

- Provide the fully-qualified paths to a set of directories that contain the annotations in the custom type system through the `-AqualDirs` option, using a colon-no-space-separated notation. For example:

```
javac -classpath /full/path/to/myProject/bin:/full/path/to/myLibrary/bin \  
      -processor org.checkerframework.common.subtyping.SubtypingChecker \  
      -AqualDirs=/full/path/to/myProject/bin:/full/path/to/myLibrary/bin MyFile.java
```

24.1.1 Compiling your qualifiers and your project

The annotations listed in `-Aquals` or `-AqualDirs` must be accessible to the compiler during compilation in the classpath. In other words, they must already be compiled (and, typically, be on the `javac` classpath) before you run the Subtyping Checker with `javac`. It is not sufficient to supply their source files on the command line.

24.1.2 Suppressing warnings from the Subtyping Checker

To suppress a warning issued by the Subtyping Checker, use a `@SuppressWarnings` annotation, with the argument being the unqualified, uncapitalized name of any of the annotations passed to `-Aquals`. This will suppress all warnings, regardless of which of the annotations is involved in the warning. (As a matter of style, you should choose one of the annotations as your `@SuppressWarnings` key and stick with it.)

24.2 Subtyping Checker example

Consider a hypothetical `Encrypted` type qualifier, which denotes that the representation of an object (such as a `String`, `CharSequence`, or `byte[]`) is encrypted. To use the Subtyping Checker for the `Encrypted` type system, follow three steps.

1. Define two annotations for the `Encrypted` and `PossiblyUnencrypted` qualifiers:

```
package myPackage.qual;

import org.checkerframework.framework.qual.DefaultFor;
import org.checkerframework.framework.qual.SubtypeOf;
import java.lang.annotation.ElementType;
import java.lang.annotation.Target;

/**
 * Denotes that the representation of an object is encrypted.
 */
@SubtypeOf(PossiblyUnencrypted.class)
@DefaultFor({TypeUseLocation.LOWER_BOUND})
@Target({ElementType.TYPE_USE, ElementType.TYPE_PARAMETER})
public @interface Encrypted {}

package myPackage.qual;

import org.checkerframework.framework.qual.DefaultQualifierInHierarchy;
import org.checkerframework.framework.qual.SubtypeOf;
import java.lang.annotation.ElementType;
import java.lang.annotation.Target;

/**
 * Denotes that the representation of an object might not be encrypted.
 */
@DefaultQualifierInHierarchy
@SubtypeOf({})
@Target({ElementType.TYPE_USE, ElementType.TYPE_PARAMETER})
public @interface PossiblyUnencrypted {}
```

Note that all custom annotations must have the `@Target(ElementType.TYPE_USE)` meta-annotation. See Section 32.5.1.

Don't forget to compile these classes:

```
$ javac myPackage/qual/Encrypted.java myPackage/qual/PossiblyUnencrypted.java
```

The resulting `.class` files should either be on your classpath, or on the processor path (set via the `-processorpath` command-line option to `javac`).

2. Write `@Encrypted` annotations in your program (say, in file `YourProgram.java`):

```

import myPackage.qual.Encrypted;

...

public @Encrypted String encrypt(String text) {
    // ...
}

// Only send encrypted data!
public void sendOverInternet(@Encrypted String msg) {
    // ...
}

void sendText() {
    // ...
    @Encrypted String ciphertext = encrypt(plaintext);
    sendOverInternet(ciphertext);
    // ...
}

void sendPassword() {
    String password = getUserPassword();
    sendOverInternet(password);
}

```

You may also need to add `@SuppressWarnings` annotations to the `encrypt` and `decrypt` methods. Analyzing them is beyond the capability of any realistic type system.

3. Invoke the compiler with the Subtyping Checker, specifying the `@Encrypted` annotation using the `-Aquals` option. You should add the `Encrypted` classfile to the processor classpath:

```
javac -processorpath myqualpath -processor org.checkerframework.common.subtyping.SubtypingChecker
```

```

YourProgram.java:42: incompatible types.
found   : @myPackage.qual.PossiblyUnencrypted java.lang.String
required: @myPackage.qual.Encrypted java.lang.String
    sendOverInternet(password);
                        ^

```

4. You can also provide the fully-qualified paths to a set of directories that contain the qualifiers using the `-AqualDirs` option, and add the directories to the boot classpath, for example:

```
javac -classpath /full/path/to/myProject/bin:/full/path/to/myLibrary/bin \
      -processor org.checkerframework.common.subtyping.SubtypingChecker \
      -AqualDirs=/full/path/to/myProject/bin:/full/path/to/myLibrary/bin YourProgram.java
```

Note that in these two examples, the compiled class file of the `myPackage.qual.Encrypted` and `myPackage.qual.PossiblyUnencrypted` annotations must exist in either the `myProject/bin` directory or the `myLibrary/bin` directory. The following placement of the class files will work with the above commands:

```

.../myProject/bin/myPackage/qual/Encrypted.class
.../myProject/bin/myPackage/qual/PossiblyUnencrypted.class

```

Also, see the example project in the `docs/examples/subtyping-extension` directory.

Figure 24.1: Type system for a type alias or typedef type system. The type system designer may choose to omit some of these types, but this is the general case. The type system designer’s choice of defaults affects the interpretation of unannotated code, which affects the guarantees given for unannotated code.

24.3 Type aliases and typedefs

A type alias or typedef is a type that shares the same representation as another type but is conceptually distinct from it. For example, some strings in your program may be street addresses; others may be passwords; and so on. You wish to indicate, for each string, which one it is, and to avoid mixing up the different types of strings. Likewise, you could distinguish integers that are offsets from those that are absolute values.

Creating a new type makes your code easier to understand by conveying the intended use of each variable. It also prevents errors that come from using the wrong type or from mixing incompatible types in an operation.

If you want to create a type alias or typedef, you have multiple options: a regular Java subtype, the Units Checker (Chapter 17, page 114), the Fake Enum Checker (Chapter 9, page 80), or the Subtyping Checker.

A Java subtype is easy to create and does not require a tool such as the Checker Framework; for instance, you would declare `class Address extends String`. There are a number of limitations to this “pseudo-typedef”, however [Goe06]. Primitive types and final types (including `String`) cannot be extended. Equality and identity tests can return incorrect results when a wrapper object is used. Existing return types in code would need to be changed, which is easy with an annotation but disruptive to change the Java type. Therefore, it is best to avoid the pseudo-typedef antipattern.

The Units Checker (Chapter 17, page 114) is useful for the particular case of units of measurement, such as kilometers verses miles.

The Fake Enum Checker (Chapter 9, page 80) builds in a set of assumptions. If those fit your use case, then it’s easiest to use the Fake Enum Checker (though you can achieve them using the Subtyping Checker). The Fake Enum Checker forbids mixing of fenums of different types, or fenums and unannotated types. For instance, binary operations other than string concatenations are forbidden, such as `NORTH+1`, `NORTH+MONDAY`, and `NORTH==MONDAY`. However, `NORTH+SOUTH` is permitted.

By default, the Subtyping Checker does not forbid any operations.

If you choose to use the Subtyping Checker, then you have an additional design choice to make about the type system. In the general case, your type system will look something like Figure 24.1.

References whose type is `@MyType` are known to store only values from your new type. There is no such guarantee for `@MyTypeUnknown` and `@NotMyType`, but those types mean different things. An expression of type `@NotMyType` is guaranteed never to evaluate to a value of your new type. An expression of type `@MyTypeUnknown` may evaluate to any value — including values of your new type and values not of your new type. (`@MyTypeBottom` is the type of `null` and is also used for dead code and erroneous situations; it can be ignored for this discussion.)

A key choice for the type system designer is which type is the default. That is, if a programmer does not write `@MyType` on a given type use, should that type use be interpreted as `@MyTypeUnknown` or as `@NotMyType`?

- If unannotated types are interpreted as `@NotMyType`, then the type system enforces very strong separation between your new type and all other types. Values of your type will never mix with values of other types. If you don’t see `@MyType` written explicitly on a type, you will know that it does not contain values of your type.
- If unannotated types are interpreted as `@MyTypeUnknown`, then a generic, unannotated type may contain a value of your new type. In this case, `@NotMyType` does not need to exist, and `@MyTypeBottom` may or may not exist in

your type system.

A downside of the stronger guarantee that comes from using `@NotMyType` as the default is the need to write additional annotations. For example, if `@NotMyType` is the default, this code does not typecheck:

```
void method(Object o) { ... }
<U> void use(List<U> list) {
    method(list.get(0));
}
```

Because (implicit) upper bounds are interpreted as the top type (see Section 26.1.2), this is interpreted as

```
void method(@NotMyType Object o) { ... }
<@U extends @MyTypeUnknown Object> void use(List<U> list) {
    // type error: list.get(0) has type @MyTypeUnknown, method expects @NotMyType
    method(list.get(0));
}
```

To make the code type-check, it is necessary to write an explicit annotation, either to restrict `use`'s argument or to expand `method`'s parameter type.

Chapter 25

Third-party checkers

The Checker Framework has been used to build other checkers that are not distributed together with the framework. This chapter mentions just a few of them. They are listed in reverse chronological order; newer ones appear first and older ones appear last.

They are externally-maintained, so if you have problems or questions, you should contact their maintainers rather than the Checker Framework maintainers.

If you want this chapter to reference your checker, please send us a link and a short description.

25.1 Object Construction Checker

The Object Construction Checker verifies that your code correctly uses the builder pattern, never omitting a required argument. The checker has built-in support for Lombok and AutoValue. Programmers can extend it to other builders by writing method specifications.

25.2 AWS crypto policy compliance checker

The AWS crypto policy compliance checker checks that no weak cipher algorithms are used with the Java crypto API.

25.3 AWS KMS compliance checker

The AWS KMS compliance checker extends the Constant Value Checker (see Chapter 21, page 127) to enforce that calls to Amazon Web Services' Key Management System only request 256-bit (or longer) data keys. This checker can be used to help enforce a compliance requirement (such as from SOC or PCI-DSS) that customer data is always encrypted with 256-bit keys.

The KMS compliance checker is available in Maven Central. To use it in `build.gradle`, add the following dependency:

```
compile group: 'software.amazon.checkerframework', name: 'aws-kms-compliance-checker', version: '1.0.2'
```

Other build systems are similar.

25.4 UI Thread Checker for ReactiveX

The Rx Thread & Effect Checker [SCSC18] enforces UI Thread safety properties for stream-based Android applications and is available at <https://github.com/uber-research/RxThreadEffectChecker>.

25.5 Glacier: Class immutability

Glacier [CNA⁺17] enforces transitive class immutability in Java. According to its webpage:

- Transitive: if a class is immutable, then every field must be immutable. This means that all reachable state from an immutable object's fields is immutable.
- Class: the immutability of an object depends only on its class's immutability declaration.
- Immutability: state in an object is not changable through any reference to the object.

25.6 SQL checker that supports multiple dialects

jOOQ is a database API that lets you build typesafe SQL queries. jOOQ version 3.0.9 and later ships with a SQL checker that provides even more safety: it ensures that you don't use SQL features that are not supported by your database implementation. You can learn about the SQL checker at <https://blog.jooq.org/2016/05/09/jsr-308-and-the-checker-framework-add-even-more-typesafety-to-jooq-3-9/>.

25.7 Read Checker for CERT FIO08-J

CERT rule FIO08-J describes a rule for the correct handling of characters/bytes read from a stream.

The Read Checker enforces this rule. It is available from <https://github.com/opprop/ReadChecker>.

25.8 Nullness Rawness Checker

The Nullness Rawness Checker is a nullness checker that uses a different type system for initialization. It was distributed with the Checker Framework through release 2.9.0 (dated 3 July 2019). If you wish to use them, install Checker Framework version 2.9.0.

25.9 Immutability checkers: IGJ, OIGJ, and Javari

Javari [TE05], IGJ [ZPA⁺07], and OIGJ [ZPL⁺10] are type systems that enforce immutability constraints. Type-checkers for all three type systems were distributed with the Checker Framework through release 1.9.13 (dated 1 April 2016). If you wish to use them, install Checker Framework version 1.9.13.

They were removed from the main distribution on June 1, 2016 because the implementations were not being maintained as the Checker Framework evolved. The type systems are valuable, and some people found the type-checkers useful. However, we wanted to focus on distributing checkers that are currently being maintained.

25.10 SPARTA information flow type-checker for Android

SPARTA is a security toolset aimed at preventing malware from appearing in an app store. SPARTA provides an information-flow type-checker that is customized to Android but can also be applied to other domains. The SPARTA toolset is available from <https://checkerframework.org/sparta/>. The paper "Collaborative verification of information flow for a high-assurance app store" appeared in CCS 2014.

25.11 CheckLT taint checker

CheckLT uses taint tracking to detect illegal information flows, such as unsanitized data that could result in a SQL injection attack. CheckLT is available from <http://checklt.github.io/>.

25.12 EnerJ checker

A checker for EnerJ [SDF⁺11], an extension to Java that exposes hardware faults in a safe, principled manner to save energy with only slight sacrifices to the quality of service, is available from <http://sampa.cs.washington.edu/research/approximation/enerj.html>.

25.13 Generic Universe Types checker

A checker for Generic Universe Types [DEM11], a lightweight ownership type system, is available from <https://ece.uwaterloo.ca/~wdietl/ownership/>.

25.14 Safety-Critical Java checker

A checker for Safety-Critical Java (SCJ, JSR 302) [TPV10] is available at <https://www.cs.purdue.edu/sss/projects/oscj/checker/checker.html>. Developer resources are available at the project page <https://code.google.com/archive/p/scj-jsr302/>.

25.15 Thread locality checker

Loci [WPM⁺09], a checker for thread locality, is available at <http://www.it.uu.se/research/upmarc/loci/>.

25.16 Units and dimensions checker

A checker for units and dimensions is available at <https://www.lexspoon.org/expannots/>.

Unlike the Units Checker that is distributed with the Checker Framework (see Section 17), this checker includes dynamic checks and permits annotation arguments that are Java expressions. This added flexibility, however, requires that you use a special version both of the Checker Framework and of the javac compiler.

25.17 Tpestate checkers

In a regular type system, a variable has the same type throughout its scope. In a tpestate system, a variable's type can change as operations are performed on it.

The most common example of tpestate is for a `File` object. Assume a file can be in two states, `@Open` and `@Closed`. Calling the `close()` method changes the file's state. Any subsequent attempt to read, write, or close the file will lead to a run-time error. It would be better for the type system to warn about such problems, or guarantee their absence, at compile time.

Just as you can extend the Subtyping Checker to create a type-checker, you can extend a tpestate checker to create a type-checker that supports tpestate analysis.

25.17.1 Comparison to flow-sensitive type refinement

The Checker Framework's flow-sensitive type refinement (Section 27.7) implements a form of tpestate analysis. For example, after code that tests a variable against null, the Nullness Checker (Chapter 3) treats the variable's type as `@NonNull T`, for some `T`.

For many type systems, flow-sensitive type refinement is sufficient. But sometimes, you need full tpestate analysis. This section compares the two. (Unused variables (Section 27.10) also have similarities with tpestate analysis and can occasionally substitute for it. For brevity, this discussion omits them.)

A tpestate analysis is easier for a user to create or extend. Flow-sensitive type refinement is built into the Checker Framework and is optionally extended by each checker. Modifying the rules requires writing Java code in your checker. By contrast, it is possible to write a simple tpestate checker declaratively, by writing annotations on the methods (such as `close()`) that change a reference's tpestate.

A tpestate analysis can change a reference's type to something that is not consistent with its original definition. For example, suppose that a programmer decides that the `@Open` and `@Closed` qualifiers are incomparable — neither is a subtype of the other. A tpestate analysis can specify that the `close()` operation converts an `@Open File` into a `@Closed File`. By contrast, flow-sensitive type refinement can only give a new type that is a subtype of the declared type — for flow-sensitive type refinement to be effective, `@Closed` would need to be a child of `@Open` in the qualifier hierarchy (and `close()` would need to be treated specially by the checker).

Chapter 26

Generics and polymorphism

This chapter describes support for Java generics (also known as “parametric polymorphism”) and polymorphism over type qualifiers.

Section 26.2 describes support for polymorphism over type qualifiers.

26.1 Generics (parametric polymorphism or type polymorphism)

The Checker Framework fully supports type-qualified Java generic types and methods (also known as “parametric polymorphism”). When instantiating a generic type, clients supply the qualifier along with the type argument, as in `List<@NonNull String>`. When using a type variable `T` within the implementation of a generic type, typically no type qualifier is written (see Section 26.1.3); rather, the instantiation of the type parameter is restricted (see Section 26.1.2).

26.1.1 Raw types

Before running any pluggable type-checker, we recommend that you eliminate raw types from your code (e.g., your code should use `List<...>` as opposed to `List`). Your code should compile without warnings when using the standard Java compiler and the `-Xlint:unchecked -Xlint:rawtypes` command-line options. Using generics helps prevent type errors just as using a pluggable type-checker does, and makes the Checker Framework’s warnings easier to understand.

If your code uses raw types, then the Checker Framework will do its best to infer the Java type arguments and the type qualifiers. By default these inferred types are ignored in subtyping checks. If you supply the command-line option `-AignoreRawTypeArguments=false` you will see errors from raw types.

26.1.2 Restricting instantiation of a generic class

When you define a generic class in Java, the `extends` clause of the generic type parameter (known as the “upper bound”) requires that the corresponding type argument must be a subtype of the bound. For example, given the definition `class G<T extends Number> {...}`, the upper bound is `Number` and a client can instantiate it as `G<Number>` or `G<Integer>` but not `G<Date>`.

You can write a type qualifier on the `extends` clause to make the upper bound a qualified type. For example, you can declare that a generic list class can hold only non-null values:

```
class MyList<T extends @NonNull Object> {...}

MyList<@NonNull String> m1;           // OK
MyList<@Nullable String> m2;         // error
```

That is, in the above example, all arguments that replace `T` in `MyList<T>` must be subtypes of `@NonNull Object`.

Syntax for upper and lower bounds

Conceptually, each generic type parameter has two bounds — a lower bound and an upper bound — and at instantiation, the type argument must be within the bounds. Java only allows you to specify the upper bound; the lower bound is implicitly the bottom type `void`. The Checker Framework gives you more power: you can specify both an upper and lower bound for type parameters. Write the upper bound on the `extends` clause, and write the lower bound on the type variable.

```
class MyList<@LowerBound T extends @UpperBound Object> { ... }
```

You may omit either the upper or the lower bound, and the Checker Framework will use a default.

For a discussion of wildcards, see Section 26.1.4.

For a concrete example, recall the type system of the Regex Checker (see Figure 11.1, page 88) in which `@Regex(0) :> @Regex(1) :> @Regex(2) :> @Regex(3) :> ...`

```
class MyRegexes<@Regex(5) T extends @Regex(1) String> { ... }
```

```
MyRegexes<@Regex(0) String> mu;    // error - @Regex(0) is not a subtype of @Regex(1)
MyRegexes<@Regex(1) String> m1;    // OK
MyRegexes<@Regex(3) String> m3;    // OK
MyRegexes<@Regex(5) String> m5;    // OK
MyRegexes<@Regex(6) String> m6;    // error - @Regex(6) is not a supertype of @Regex(5)
```

The above declaration states that the upper bound of the type variable is `@Regex(1) String` and the lower bound is `@Regex(5) void`. That is, arguments that replace `T` in `MyList<T>` must be subtypes of `@Regex(1) String` and supertypes of `@Regex(5) void`. Since `void` cannot be used to instantiate a generic class, `MyList` may be instantiated with `@Regex(1) String` through `@Regex(5) String`.

To specify an exact bound, place the same annotation on both bounds. For example:

```
class MyListOfNonNulls<@NonNull T extends @NonNull Object> { ... }
class MyListOfNullables<@Nullable T extends @Nullable Object> { ... }

MyListOfNonNulls<@NonNull Number> v1;    // OK
MyListOfNonNulls<@Nullable Number> v2;   // error
MyListOfNullables<@NonNull Number> v4;   // error
MyListOfNullables<@Nullable Number> v3;  // OK
```

It is an error if the lower bound is not a subtype of the upper bound.

```
class MyClass<@Nullable T extends @NonNull Object> // error: @Nullable is not a supertype of @NonNull
```

Defaults

A generic type parameter or wildcard is written as `class MyClass<@LowerBound T extends @UpperBound JavaUpperBound>` or as `MyClass<@UpperBound ? super @LowerBound JavaLowerBound>`, where “`@LowerBound`” and “`@UpperBound`” are type qualifiers.

For lower bounds: If no type annotation is written in front of `?`, then the lower bound defaults to `@BottomType void`.

For upper bounds:

- If the `extends` clause is omitted, then the upper bound defaults to `@TopType Object`.
- If the `extends` clause is written but contains no type qualifier, then the normal defaulting rules apply to the type in the `extends` clause (see Section 27.5.3).

The upper-bound rules mean that even though in Java the following two declarations are equivalent:

```
class MyClass<T>
class MyClass<T extends Object>
```

they specify different type qualifiers on the upper bound, if the type system's default annotation is not its top annotation. The Nullness type system is an example.

```
class MyClass<T> == class MyClass<T extends @Nullable Object>
class MyClass<T extends Object> == class MyClass<T extends @NonNull Object>
```

The rationale for this choice is:

- The “<T>” in `MyClass<T>` means “fully unconstrained”, and the rules maintain that, without the need for a programmer to change existing code.
- The “Object” in `MyClass<T extends Object>` is treated exactly like every other occurrence of `Object` in the program — it would be confusing for different occurrences of `Object` to mean different annotated types.

Because of these rules, the recommended style is:

- Use “<T>” when there are no constraints on the type qualifiers. This is short and is what already appears in source code.
- Whenever you write an `extends` clause, write an explicit type annotation on it. For example, for the Nullness Checker, write `class MyClass<T>` rather than `class MyClass<T extends @Nullable Object>`, and write `class MyClass<T extends @NonNull Object>` rather than `class MyClass<T extends Object>`.

For further discussion, see Section 34.7.2.

26.1.3 Type annotations on a use of a generic type variable

A type annotation on a use of a generic type variable overrides/ignores any type qualifier (in the same type hierarchy) on the corresponding actual type argument. For example, suppose that `T` is a formal type parameter. Then using `@Nullable T` within the scope of `T` applies the type qualifier `@Nullable` to the (unqualified) Java type of `T`. This feature is sometimes useful, but more often the implementation of a generic type just uses the type variable `T`, whose instantiation is restricted (see Section 26.1.2).

Here is an example of applying a type annotation to a generic type variable:

```
class MyClass2<T> {
    ...
    @Nullable T myField = null;
    ...
}
```

The type annotation does not restrict how `MyClass2` may be instantiated. In other words, both `MyClass2<@NonNull String>` and `MyClass2<@Nullable String>` are legal, and in both cases `@Nullable T` means `@Nullable String`. In `MyClass2<@Interned String>`, `@Nullable T` means `@Nullable @Interned String`.

Defaulting never affects a use of a type variable, even if the type variable use has no explicit annotation. Defaulting helps to choose a single type qualifier for a concrete Java class or interface. By contrast, a type variable use represents a set of possible types.

26.1.4 Annotations on wildcards

At an instantiation of a generic type, a Java wildcard indicates that some constraints are known on the type argument, but the type argument is not known exactly. For example, you can indicate that the type parameter for variable `ls` is some unknown subtype of `CharSequence`:

```
List<? extends CharSequence> ls;
ls = new ArrayList<String>();    // OK
ls = new ArrayList<Integer>();  // error: Integer is not a subtype of CharSequence
```

For more details about wildcards, see the Java tutorial on wildcards or JLS §4.5.1.

You can write a type annotation on the bound of a wildcard:

```
List<? extends @NonNull CharSequence> ls;
ls = new ArrayList<@NonNull String>();    // OK
ls = new ArrayList<@Nullable String>();  // error: @Nullable is not a subtype of @NonNull
```

Conceptually, every wildcard has two bounds — an upper bound and a lower bound. Java only permits you to write one bound. You can specify the upper bound with `<? extends SomeType>`, in which case the lower bound is implicitly the bottom type `void`. You can specify the lower bound (with `<? super OtherType>`), in which case the upper bound is implicitly the top type `Object`. The Checker Framework is more flexible: it lets you similarly write annotations on both the upper and lower bound.

To annotate the *implicit* bound, write the type annotation before the `?`. For example:

```
List<@LowerBound ? extends @UpperBound CharSequence> ls;
List<@UpperBound ? super @NonNull Number> ls;
```

For an unbounded wildcard (`<?>`, with neither bound specified), the annotation in front of a wildcard applies to both bounds. The following three declarations are equivalent (except that you cannot write the bottom type `void`; note that `Void` does not denote the bottom type):

```
List<@NonNull ?> lnn;
List<@NonNull ? extends @NonNull Object> lnn;
List<@NonNull ? super @NonNull void> lnn;
```

Note that the annotation in front of a type parameter always applies to its lower bound, because type parameters can only be written with `extends` and never `super`.

The defaulting rules for wildcards also differ from those of type parameters (see Section 27.5.5).

26.1.5 Examples of qualifiers on a type parameter

Recall that `@Nullable X` is a supertype of `@NonNull X`, for any `X`. Most of the following types mean different things:

```
class MyList1<@Nullable T> { ... }
class MyList1a<@Nullable T extends @Nullable Object> { ... } // same as MyList1
class MyList2<@NonNull T extends @NonNull Object> { ... }
class MyList2a<T extends @NonNull Object> { ... } // same as MyList2
class MyList3<T extends @Nullable Object> { ... }
```

`MyList1` and `MyList1a` must be instantiated with a nullable type. The implementation of `MyList1` must be able to consume (store) a null value and produce (retrieve) a null value.

`MyList2` and `MyList2a` must be instantiated with non-null type. The implementation of `MyList2` has to account for only non-null values — it does not have to account for consuming or producing null.

`MyList3` may be instantiated either way: with a nullable type or a non-null type. The implementation of `MyList3` must consider that it may be instantiated either way — flexible enough to support either instantiation, yet rigorous enough to impose the correct constraints of the specific instantiation. It must also itself comply with the constraints of the potential instantiations.

One way to express the difference among `MyList1`, `MyList2`, and `MyList3` is by comparing what expressions are legal in the implementation of the list — that is, what expressions may appear in the ellipsis in the declarations above, such as inside a method's body. Suppose each class has, in the ellipsis, these declarations:

```

T t;
@Nullable T nble;      // Section "Type annotations on a use of a generic type variable", below,
@NonNull T nn;        // further explains the meaning of "@Nullable T" and "@NonNull T".
void add(T arg) {}
T get(int i) {}

```

Then the following expressions would be legal, inside a given implementation — that is, also within the ellipses. (Compilable source code appears as file `checker-framework/checker/tests/nullness/generics/GenericsExample.java`.)

	MyList1	MyList2	MyList3
<code>t = null;</code>	OK	error	error
<code>t = nble;</code>	OK	error	error
<code>nble = null;</code>	OK	OK	OK
<code>nn = null;</code>	error	error	error
<code>t = this.get(0);</code>	OK	OK	OK
<code>nble = this.get(0);</code>	OK	OK	OK
<code>nn = this.get(0);</code>	error	OK	error
<code>this.add(t);</code>	OK	OK	OK
<code>this.add(nble);</code>	OK	error	error
<code>this.add(nn);</code>	OK	OK	OK

The differences are more significant when the qualifier hierarchy is more complicated than just `@Nullable` and `@NonNull`.

26.1.6 Covariant type parameters

Java types are *invariant* in their type parameter. This means that `A<X>` is a subtype of `B<Y>` only if `X` is identical to `Y`. For example, `ArrayList<Number>` is a subtype of `List<Number>`, but neither `ArrayList<Integer>` nor `List<Integer>` is a subtype of `List<Number>`. (If they were, there would be a loophole in the Java type system.) For the same reason, type parameter annotations are treated invariantly. For example, `List<@Nullable String>` is not a subtype of `List<String>`.

When a type parameter is used in a read-only way — that is, when values of that type are read but are never assigned — then it is safe for the type to be *covariant* in the type parameter. Use the `@Covariant` annotation to indicate this. When a type parameter is covariant, two instantiations of the class with different type arguments have the same subtyping relationship as the type arguments do.

For example, consider `Iterator`. Its elements can be read but not written, so `Iterator<@Nullable String>` can be a subtype of `Iterator<String>` without introducing a hole in the type system. Therefore, its type parameter is annotated with `@Covariant`. The first type parameter of `Map.Entry` is also covariant. Another example would be the type parameter of a hypothetical class `ImmutableList`.

The `@Covariant` annotation is trusted but not checked. If you incorrectly specify as covariant a type parameter that can be written (say, the class performs a `set` operation or some other mutation on an object of that type), then you have created an unsoundness in the type system. For example, it would be incorrect to annotate the type parameter of `ListIterator` as covariant, because `ListIterator` supports a `set` operation.

26.1.7 Method type argument inference and type qualifiers

Sometimes method type argument inference does not interact well with type qualifiers. In such situations, you might need to provide explicit method type arguments, for which the syntax is as follows:

```

Collections.<@MyTypeAnnotation Object>sort(l, c);

```

This uses Java's existing syntax for specifying a method call's type arguments.

26.1.8 The Bottom type

Many type systems have a `*Bottom` type that is used only for the `null` value, dead code, and some erroneous situations. A programmer should rarely write the bottom type.

One use is on a lower bound, to indicate that any type qualifier is permitted. A lower-bounded wildcard indicates that a consumer method can accept a collection containing any Java type above some Java type, and you can add the bottom type qualifier as well:

```
public static void addNumbers(List<? super @SignednessBottom Integer> list) { ... }
```

26.2 Qualifier polymorphism

The Checker Framework supports type *qualifier* polymorphism for methods, which permits a single method to have multiple different qualified type signatures. This is similar to Java's generics, but is used in situations where you cannot use Java generics. If you can use generics, you typically do not need to use a polymorphic qualifier such as `@PolyNull`.

To *use* a polymorphic qualifier, just write it on a type. For example, you can write `@PolyNull` anywhere in a method that you would write `@NonNull` or `@Nullable`. A polymorphic qualifier can be used in a method signature or body. It may not be used on a class or field.

A method written using a polymorphic qualifier conceptually has multiple versions, somewhat like the generics feature of Java or a template in C++. In each version, each instance of the polymorphic qualifier has been replaced by the same other qualifier from the hierarchy. See the examples below in Section 26.2.1.

The method body must type-check with all signatures. A method call is type-correct if it type-checks under any one of the signatures. If a call matches multiple signatures, then the compiler uses the most specific matching signature for the purpose of type-checking. This is the same as Java's rule for resolving overloaded methods.

To *define* a polymorphic qualifier, mark the definition with `@PolymorphicQualifier`. For example, `@PolyNull` is a polymorphic type qualifier for the Nullness type system:

```
import java.lang.annotation.ElementType;
import java.lang.annotation.Target;
import org.checkerframework.framework.qual.PolymorphicQualifier;

@PolymorphicQualifier
@Target({ElementType.TYPE_USE, ElementType.TYPE_PARAMETER})
public @interface PolyNull {}
```

26.2.1 Examples of using polymorphic qualifiers

As an example of the use of `@PolyNull`, method `Class.cast` returns `null` if and only if its argument is `null`:

```
@PolyNull T cast(@PolyNull Object obj) { ... }
```

This is like writing:

```
@NonNull T cast(@NonNull Object obj) { ... }
@Nullable T cast(@Nullable Object obj) { ... }
```

except that the latter is not legal Java, since it defines two methods with the same Java signature.

As another example, consider

```
// Returns null if either argument is null.
@PolyNull T max(@PolyNull T x, @PolyNull T y);
```

which is like writing

```
@NonNull T max( @NonNull T x, @NonNull T y);
@Nullable T max(@Nullable T x, @Nullable T y);
```

At a call site, the most specific applicable signature is selected.

Another way of thinking about which one of the two `max` variants is selected is that the nullness annotations of (the declared types of) both arguments are *unified* to a type that is a supertype of both, also known as the *least upper bound* or lub. If both arguments are `@NonNull`, their unification (lub) is `@NonNull`, and the method return type is `@NonNull`. But if even one of the arguments is `@Nullable`, then the unification (lub) is `@Nullable`, and so is the return type.

26.2.2 Relationship to subtyping and generics

Qualifier polymorphism has the same purpose and plays the same role as Java's generics. You use them in the same cases, such as:

- A method operates on collections with different types of elements.
- Two different arguments have the same type, without constraining them to be one specific type.
- A method returns a value of the same type as its argument.

If a method is written using Java generics, it usually does not need qualifier polymorphism. If you can use Java's generics, then that is often better. On the other hand, if you have legacy code that is not written generically, and you cannot change it to use generics, then you can use qualifier polymorphism to achieve a similar effect, with respect to type qualifiers only. The Java compiler still treats the base Java types non-generically.

In some cases, you don't need qualifier polymorphism because subtyping already provides the needed functionality. `String` is a supertype of `@Interned String`, so a method `toUpperCase` that is declared to take a `String` parameter can also be called on an `@Interned String` argument.

26.2.3 Using multiple polymorphic qualifiers in a method signature

Usually, it does not make sense to write only a single instance of a polymorphic qualifier in a method definition: if you write one instance of (say) `@PolyNull`, then you should use at least two. The main benefit of polymorphic qualifiers comes when one is used multiple times in a method, since then each instance turns into the same type qualifier. (Section 26.2.4 describes some exceptions to this rule: times when it makes sense to write a single polymorphic qualifier in a signature.)

Most frequently, the polymorphic qualifier appears on at least one formal parameter and also on the return type.

It can also be useful to have polymorphic qualifiers on (only) multiple formal parameters, especially if the method side-effects one of its arguments. For example, consider

```
void moveBetweenStacks(Stack<@PolyNull Object> s1, Stack<@PolyNull Object> s2) {
    s1.push(s2.pop());
}
```

In this particular example, it would be cleaner to rewrite your code to use Java generics, if you can do so:

```
<T> void moveBetweenStacks(Stack<T> s1, Stack<T> s2) {
    s1.push(s2.pop());
}
```

26.2.4 Using a single polymorphic qualifier in a method signature

As explained in Section 26.2.3, you will usually use a polymorphic qualifier multiple times in a signature. This section describes situations when it makes sense to write just one polymorphic qualifier in a method signature. Some of these situations can be avoided by writing a generic method, but in legacy code it may not be possible for you to change a method to be generic.

Using a single polymorphic qualifier on a return type

It is unusual, but permitted, to write just one polymorphic qualifier, on a return type.

This is just like it is unusual, but permitted, to write just one occurrence of a generic type parameter, on a return type. An example of such a method is `Collections.emptyList()`.

Using a single polymorphic qualifier on an element type

It can make sense to use a polymorphic qualifier just once, on an array or generic element type.

For example, consider a routine that returns the index, in an array, of a given element:

```
public static int indexOf(@Polymorphic Object[] a, @Polymorphic Object elt) { ... }
```

If `@Polymorphic` were replaced with either `@Nullable` or `@NonNull`, then one of these safe client calls would be rejected:

```
@Nullable Object[] a1;  
@NonNull Object[] a2;  
  
indexOf(a1, someObject);  
indexOf(a2, someObject);
```

Of course, it would be better style to use a generic method, as in either of these signatures:

```
public static <T extends @Polymorphic Object> int indexOf(T[] a, @Polymorphic Object elt) { ... }  
public static <T extends @Polymorphic Object> int indexOf(T[] a, T elt) { ... }
```

Another example is a method that writes bytes to a file. It accepts an array of signed or unsigned bytes, and it behaves identically for both:

```
void write(@Polymorphic byte[] b) { ... }
```

These examples use arrays, but there are similar examples that use collections.

Don't use a single polymorphic qualifier on a formal parameter type

There is no point to writing

```
void m(@Polymorphic Object obj)
```

which expands to

```
void m(@NonNull Object obj)  
void m(@Nullable Object obj)
```

This is no different (in terms of which calls to the method will type-check) than writing just

```
void m(@Nullable Object obj)
```

Chapter 27

Advanced type system features

This chapter describes features that are automatically supported by every checker written with the Checker Framework. You may wish to skim or skip this chapter on first reading. After you have used a checker for a little while and want to be able to express more sophisticated and useful types, or to understand more about how the Checker Framework works, you can return to it.

27.1 Invariant array types

Java's type system is unsound with respect to arrays. That is, the Java type-checker approves code that is unsafe and will cause a run-time crash. Technically, the problem is that Java has "covariant array types", such as treating `String[]` as a subtype of `Object[]`. Consider the following example:

```
String[] strings = new String[] {"hello"};
Object[] objects = strings;
objects[0] = new Object();
String myString = str[0];
```

The above code puts an `Object` in the array `strings` and thence in `myString`, even though `myString = new Object()` should be, and is, rejected by the Java type system. Java prevents corruption of the JVM by doing a costly run-time check at every array assignment; nonetheless, it is undesirable to learn about a type error only via a run-time crash rather than at compile time.

When you pass the `-AinvariantArrays` command-line option, the Checker Framework is stricter than Java, in the sense that it treats arrays invariantly rather than covariantly. This means that a type system built upon the Checker Framework is sound: you get a compile-time guarantee without the need for any run-time checks. But it also means that the Checker Framework rejects code that is similar to what Java unsoundly accepts. The guarantee and the compile-time checks are about your extended type system. The Checker Framework does not reject the example code above, which contains no type annotations.

Java's covariant array typing is sound if the array is used in a read-only fashion: that is, if the array's elements are accessed but the array is not modified. However, facts about read-only usage are not built into any of the type-checkers. Therefore, when using type systems along with `-AinvariantArrays`, you will need to suppress any warnings that are false positives because the array is treated in a read-only way.

27.2 Context-sensitive type inference for array constructors

When you write an expression, the Checker Framework gives it the most precise possible type, depending on the particular expression or value. For example, when using the Regex Checker (Chapter 11, page 87), the string `"hello"`

is given type `@Regex String` because it is a legal regular expression (whether it is meant to be used as one or not) and the string `"(foo"` is given the type `@RegexBottom String` because it is not a legal regular expression.

Array constructors work differently. When you create an array with the array constructor syntax, such as the right-hand side of this assignment:

```
String[] myStrings = {"hello"};
```

then the expression does not get the most precise possible type, because doing so could cause inconvenience. Rather, its type is determined by the context in which it is used: the left-hand side if it is in an assignment, the declared formal parameter type if it is in a method call, etc.

In particular, if the expression `{"hello"}` were given the type `@Regex String[]`, then the assignment would be illegal! But the Checker Framework gives the type `String[]` based on the assignment context, so the code type-checks.

If you prefer a specific type for a constructed array, you can indicate that either in the context (change the declaration of `myStrings`) or in a new construct (change the expression to `new @Regex String[] {"hello"}`).

27.3 Upper bound of qualifiers on uses of a given type

The examples in this section use the type qualifier hierarchy `@A > @B > @C`.

A qualifier on a use of a certain type must be a subtype or equal to the upper bound for that type. The upper bound of qualifiers used on a given type is specified by annotating the type declaration with some qualifier.

```
@C class MyClass {}
```

This means that `@B MyClass` is an invalid type. (Annotations on class declarations may also specify default annotations for uses of the type; see Section 27.5.1)

An upper bound can also be specified by the type-system designer using the meta-annotation `@UpperBoundFor`.

If no annotation is present on a type declaration and if no `@UpperBoundFor` mentions the type, then the bound is top. This can be changed by overriding `AnnotatedTypeFactory#getTypeDeclarationBounds`.

There are two exceptions.

- An expression can have a supertype of the upper bound; that is, some expression could have type `@B MyClass`. This type is not written explicitly, but results from viewpoint adaptation.
- Using usual CLIMB-to-top rules, local variables of type `MyClass` default to `@A MyClass`. It is legal for `@A MyClass` to be the type of a local variable. For consistency, users are allowed to write such a type on a local variable declaration.

Due to existing type rules, an expression of type `A MyClass` can only be used in limited ways.

- Since every field, formal parameter, and return type of type `MyClass` (or lower) is annotated as `@B` (or lower), it cannot be assigned to a field, passed to a method, or returned from a method.
- It can be used in a context that requires `@A Object` (or whatever the least supertype is of `MyClass` for which the `@A` qualifier is permitted). Examples include being tested against `null` or (for most type systems) being passed to polymorphic routines such as `System.out.println` or `System.identityHashCode`.

These operations might refine its type. If a user wishes to annotate a method that does type refinement, its formal parameter must be of illegal type `@A MyClass`, which requires a warning suppression.

If the framework forbid expressions and local variables from having types inconsistent with the class annotation, then important APIs and common coding paradigms will no longer type-check.

Consider the annotation

```
@NonNull class Optional { ... }
```

and the client code

```

Map<String, Optional> m;
String key = ...;
Optional value = m.get(key);
if (value != null) {
    ...;
}

```

The type of `m.get(key)` is `@Nullable Optional`, which is an illegal type. However, this is a very common paradigm. Programmers should not need to rewrite the code to test `m.containsKey(key)` nor suppress a warning in this safe code.

27.4 The effective qualifier on a type (defaults and inference)

A checker sometimes treats a type as having a slightly different qualifier than what is written on the type — especially if the programmer wrote no qualifier at all. Most readers can skip this section on first reading, because you will probably find the system simply “does what you mean”, without forcing you to write too many qualifiers in your program. In particular, qualifiers in method bodies are rare (except occasionally on type arguments and array component types).

The following steps determine the effective qualifier on a type — the qualifier that the checkers treat as being present.

1. If a type qualifier is present in the source code, that qualifier is used.
2. If there is no explicit qualifier on a type, then a default qualifier is applied; see Section 27.5. Defaulted qualifiers are treated by checkers exactly as if the programmer had written them explicitly.
3. The type system may refine a qualified type on a local variable — that is, treat it as a subtype of how it was declared or defaulted. This refinement is always sound and has the effect of eliminating false positive error messages. See Section 27.7.

27.5 Default qualifier for unannotated types

An unannotated Java type is treated as if it had a default annotation. Both the type system designer and an end-user programmer can control the defaulting. Defaulting never applies to uses of type variables, even if they do not have an explicit type annotation. Most of this section is about defaults for source code that is read by the compiler. When the compiler reads a `.class` file, different defaulting rules apply. See Section 27.5.6 for these rules.

There are several defaulting mechanisms, for convenience and flexibility. When determining the default qualifier for a use of an unannotated type, `MyClass`, the following rules are used in order, until one applies.

1. The qualifier specified via `@DefaultQualifierForUse` on the declaration of the `MyClass`. (Section 27.5.1)
2. If no `@NoDefaultQualifierForUse` is written on the declaration of `MyClass`, the qualifier explicitly written on the declaration of `MyClass`. (Section 27.5.1)
3. The qualifier with a meta-annotation `@DefaultFor(types = MyClass.class)`. (Section 27.5.1)
4. The qualifier with a meta-annotation `@DefaultFor(typeKinds = KIND)`, where `KIND` is the `TypeKind` of `MyClass`. (Section 27.5.1)
5. The qualifier in the innermost user-written `@DefaultQualifier` for the location of the use of `MyClass`. (Section 27.5.2)
6. The qualifier in the meta-annotation `@DefaultFor` for the location of the use of `MyClass`. These are defaults specified by the type system designer (Section 32.5.4); this is usually **CLIMB-to-top** (Section 27.5.3) (**CLIMB** means **C**asts, **L**ocals, **I**nstanceof, and (some) **iM**plicit **B**ounds).
7. The qualifier with the meta-annotation `@DefaultQualifierInHierarchy`

If the unannotated type is the type of a local variable, then the first 5 rules are skipped and only rules 6 and 7 apply. If rule 6 applies, it makes the type of local variables top so they can be refined.

27.5.1 Default for use of a type

The type declaration annotation `@DefaultQualifierForUse` indicates that the specified qualifier should be added to all unannotated uses of the type.

For example:

```
@DefaultQualifierForUse(B.class)
class MyClass {}
```

This means any unannotated use of `MyClass` is treated as `@B MyClass` by the checker. (Except for locals, which can be refined.)

Similarly, the meta-annotation `@DefaultFor` can be used to specify defaults for uses of of types, using the `types` element, or type kinds, using the `typeKinds` elements.

Interaction between qualifier bounds and `DefaultQualifierForUse`:

- If a type declaration is annotated with a qualifier bound, but not a `@DefaultQualifierForUse`, then the qualifier bound is added to all unannotated uses of that type (except locals). For example, `@C class MyClass` is equivalent to

```
@DefaultQualifierForUse(C.class)
@C class MyClass {}
```

- If the qualifier bound should not be added to all unannotated uses, then `@NoDefaultQualifierForUse` should be written on the declaration:

```
@NoDefaultQualifierForUse
@C class MyClass {}
```

This means that unannotated uses of `MyClass` are defaulted normally.

- If neither `@DefaultQualifierForUse` nor a qualifier bound is present on a type declaration, that is equivalent to writing `@NoDefaultQualifierForUse`.

27.5.2 Controlling defaults in source code

The end-user programmer specifies a default qualifier by writing the `@DefaultQualifier(ClassName, [locations])` annotation on a package, class, method, or variable declaration. The argument to `@DefaultQualifier` is the `Class` name of an annotation. The optional second argument indicates where the default applies. If the second argument is omitted, the specified annotation is the default in all locations. See the Javadoc of `DefaultQualifier` for details.

For example, using the Nullness type system (Chapter 3):

```
import org.checkerframework.framework.qual.DefaultQualifier;
import org.checkerframework.checker.nullness.qual.NonNull;

@DefaultQualifier(NonNull.class)
class MyClass {

    public boolean compile(File myFile) { // myFile has type "@NonNull File"
        if (!myFile.exists())           // no warning: myFile is non-null
            ...
        @Nullable File srcPath = ...; // must annotate to specify "@Nullable File"
        if (srcPath.exists())           // warning: srcPath might be null
            ...
    }

    @DefaultQualifier(Tainted.class)
    public boolean isJavaFile(File myFile) { // myFile has type "@Tainted File"
```

```
    ...
}
}
```

You may write multiple `@DefaultQualifier` annotations at a single location.

If `@DefaultQualifier[s]` is placed on a package (via the `package-info.java` file), then it applies to the given package *and* all subpackages.

27.5.3 Defaulting rules and CLIMB-to-top

Each type system defines a default qualifier (see Section 32.5.4). For example, the default qualifier for the Nullness Checker is `@NonNull`. When a user writes an unqualified type such as `Date`, the Nullness Checker interprets it as `@NonNull Date`.

The type system applies that default qualifier to most but not all type uses. In particular, unless otherwise stated, every type system uses the CLIMB-to-top rule. This rule states that the *top* qualifier in the hierarchy is the default for the CLIMB locations: **C**asts, **L**ocals, **I**nstanceof, and (some) **iM**plicit **B**ounds. For example, when the user writes an unqualified type such as `Date` in such a location, the Nullness Checker interprets it as `@Nullable Date` (because `@Nullable` is the top qualifier in the hierarchy, see Figure 3.1).

The CLIMB-to-top rule is used only for unannotated source code that is being processed by a checker. For unannotated libraries (code read by the compiler in `.class` or `.jar` form), see Section 27.5.6.

The rest of this section explains the rationale and implementation of CLIMB-to-top.

Here is the rationale for CLIMB-to-top:

- Local variables are defaulted to top because type refinement (Section 27.7) is applied to local variables. If a local variable starts as the top type, then the Checker Framework refines it to the best (most specific) possible type based on assignments to it. As a result, a programmer rarely writes an explicit annotation on any of those locations.
Variables defaulted to top include local variables, resource variables in the try-with-resources construct, variables in `for` statements, and `catch` arguments (known as exception parameters in the Java Language Specification). Exception parameters need to have the top type because exceptions of arbitrary qualified types can be thrown and the Checker Framework does not provide run-time checks.
- Cast and instanceof types are given the same type as their argument expression. This has the same effect as if they were given the top type and then flow-sensitively refined to the type of their argument. However, note that programmer-written type qualifiers are *not* refined.
- Implicit upper bounds are defaulted to top to allow them to be instantiated in any way. If a user declared `class C<T> { ... }`, then the Checker Framework assumes that the user intended to allow any instantiation of the class, and the declaration is interpreted as `class C<T extends @Nullable Object> { ... }` rather than as `class C<T extends @NonNull Object> { ... }`. The latter would forbid instantiations such as `C<@Nullable String>`, or would require rewriting of code. On the other hand, if a user writes an explicit bound such as `class C<T extends D> { ... }`, then the user intends some restriction on instantiation and can write a qualifier on the upper bound as desired.
This rule means that the upper bound of `class C<T>` is defaulted differently than the upper bound of `class C<T extends Object>`. This may seem confusing, but it is the least bad option. The more confusing alternative would be for “Object” to be defaulted differently in `class C<T extends Object>` and in an instantiation `C<Object>`, and for the upper bounds to be defaulted differently in `class C<T extends Object>` and `class C<T extends Date>`.
- Implicit *lower* bounds are defaulted to the bottom type, again to allow maximal instantiation. Note that Java does not allow a programmer to express both the upper and lower bounds of a type, but the Checker Framework allows the programmer to specify either or both; see Section 26.1.2.

A `@DefaultQualifier` that specifies a CLIMB-to-top location takes precedence over the CLIMB-to-top rule.

Here is how the Nullness Checker overrides part of the CLIMB-to-top rule:

```

@DefaultQualifierInHierarchy
@DefaultFor({ TypeUseLocation.EXCEPTION_PARAMETER })
public @interface NonNull {}

public @interface Nullable {}

```

As mentioned above, the exception parameters are always non-null, so `@DefaultFor({ TypeUseLocation.EXCEPTION_PARAMETER })` on `@NonNull` overrides the CLIMB-to-top rule.

27.5.4 Inherited defaults

In certain situations, it would be convenient for an annotation on a superclass member to be automatically inherited by subclasses that override it. Such a feature would reduce annotation effort, but it would also reduce program comprehensibility. In general, a program is read more often than it is edited/annotated, so the Checker Framework does not currently support this feature.

Currently, a user can determine the annotation on a parameter or return value by looking at a single file. If annotations could be inherited from supertypes, then a user would have to examine all supertypes, and do computations over them, to understand the meaning of an unannotated type in a given file.

Computation is necessary because different annotations might be inherited from a supertype and an interface, or from two interfaces. For return types, the inherited type should be the least upper bound of all annotations on overridden implementations in supertypes. For method parameters, the inherited type should be the greatest lower bound of all annotations on overridden implementations in supertypes. In each case, an error would be thrown if no such annotations existed.

In the future, this feature may be added optionally, and each type-checker implementation can enable it if desired.

27.5.5 Inherited wildcard annotations

If a wildcard is unbounded and has no annotation (e.g. `List<?>`), the annotations on the wildcard's bounds are copied from the type parameter to which the wildcard is an argument.

For example, the two wildcards in the declarations below are equivalent.

```

class MyList<@Nullable T extends @Nullable Object> {}

MyList<?> listOfNullables;
MyList<@Nullable ? extends @Nullable Object> listOfNullables;

```

The Checker Framework copies these annotations because wildcards must be within the bounds of their corresponding type parameter. By contrast, if the bounds of a wildcard were defaulted differently from the bounds of its corresponding type parameter, then there would be many false positive `type.argument.type.incompatible` warnings.

Here is another example of two equivalent wildcard declarations:

```

class MyList<@Regex(5) T extends @Regex(1) Object> {}

MyList<?> listOfRegexes;
MyList<@Regex(5) ? extends @Regex(1) Object> listOfRegexes;

```

Note, this copying of annotations for a wildcard's bounds applies only to unbounded wildcards. The two wildcards in the following example are equivalent.

```

class MyList<@NonNull T extends @Nullable Object> {}

MyList<? extends Object> listOfNonNulls;
MyList<@NonNull ? extends @NonNull Object> listOfNonNulls2;

```

Note, the upper bound of the wildcard `? extends Object` is defaulted to `@NonNull` using the CLIMB-to-top rule (see Section 27.5.3). Also note that the `MyList` class declaration could have been more succinctly written as: `class MyList<T extends @Nullable Object>` where the lower bound is implicitly the bottom annotation: `@NonNull`.

27.5.6 Default qualifiers for `.class` files (library defaults)

(*Note:* Currently, the conservative library defaults presented in this section are off by default and can be turned on by supplying the `-AuseConservativeDefaultsForUncheckedCode=bytecode` command-line option. In a future release, they will be turned on by default and it will be possible to turn them off by supplying a `-AuseConservativeDefaultsForUncheckedCode` command-line option.)

The defaulting rules presented so far apply to source code that is read by the compiler. When the compiler reads a `.class` file, different defaulting rules apply.

If the checker was run during the compiler execution that created the `.class` file, then there is no need for defaults: the `.class` file has an explicit qualifier at each type use. (Furthermore, unless warnings were suppressed, those qualifiers are guaranteed to be correct.) When you are performing pluggable type-checking, it is best to ensure that the compiler only reads such `.class` files. Section 31.4 discusses how to create annotated libraries.

If the checker was not run during the compiler execution that created the `.class` file, then the `.class` file contains only the type qualifiers that the programmer wrote explicitly. (Furthermore, there is no guarantee that these qualifiers are correct, since they have not been checked.) In this case, each checker decides what qualifier to use for the locations where the programmer did not write an annotation. Unless otherwise noted, the choice is:

- For method parameters and lower bounds, use the bottom qualifier (see Section 32.5.7).
- For method return values, fields, and upper bounds, use the top qualifier (see Section 32.5.7).

These choices are conservative. They are likely to cause many false-positive type-checking errors, which will help you to know which library methods need annotations. You can then write those library annotations (see Chapter 31) or alternately suppress the warnings (see Chapter 28).

For example, an unannotated method

```
String concatenate(String p1, String p2)
```

in a classfile would be interpreted as

```
@Top String concatenate(@Bottom String p1, @Bottom String p2)
```

There is no single possible default that is sound for fields. In the rare circumstance that there is a mutable public field in an unannotated library, the Checker Framework may fail to warn about code that can misbehave at run time.

27.6 Annotations on constructors

27.6.1 Annotations on constructor declarations

An annotation on the “return type” of a constructor declaration indicates what the constructor creates. For example,

```
@B class MyClass {  
    @C MyClass() {}  
}
```

means that invoking that constructor creates a `@C MyClass`.

The Checker Framework cannot verify that the constructor really creates such an object, because the Checker Framework does not know the type-system-specific semantics of the `@C` annotation. Therefore, if the constructor result type is different than the top annotation in the hierarchy, the Checker Framework will issue a warning. The programmer should check the annotation manually, then suppress the warning.

Defaults

If a constructor declaration is unannotated, it defaults to the same type as that of its enclosing class (rather than the default qualifier in the hierarchy). For example, the Tainting Checker (Chapter 10) has `@Tainted` as its default qualifier. Consider the following class:

```
@Untainted class MyClass {  
    MyClass() {}  
}
```

The constructor declaration is equivalent to `@Untainted MyClass() {}`.

The Checker Framework produces the same error messages for explicitly-written and defaulted annotations.

27.6.2 Annotations on constructor invocations

The type of a method call expression `x.myMethod(y, z)` is determined by the return type of the declaration of `myMethod`. There is no way to write an annotation on the call to change its type. However, it is possible to write a cast: `(@Anno SomeType) x.myMethod(y, z)`. The Checker Framework will issue a warning that it cannot verify that the downcast is correct. The programmer should manually determine that the annotation is correct and then suppress the warning.

A constructor invocation `new MyClass()` is also a call, so its semantics are similar. The type of the expression is determined by the annotation on the result type of the constructor declaration. It is possible to write a cast `(@Anno MyClass) new MyClass()`. The syntax `new @Anno MyClass()` is shorthand for the cast. For either syntax, the Checker Framework will issue a warning that it cannot verify that the cast is correct. The programmer may suppress the warning if the code is correct.

27.7 Type refinement (flow-sensitive type qualifier inference)

The checkers treat expressions within a method body as having a subtype of their declared or defaulted (Section 27.5) type.

Type refinement eliminates some false positive warnings. Type refinement also reduces your burden of writing type qualifiers in your program, since you do not need to write type qualifiers on local variables.

27.7.1 Type refinement examples

Here is an example for the Nullness Checker (Chapter 3, page 27). `myVar` is declared as `@Nullable String`, but it is treated as `@NonNull String` within the body of the `if` test.

```
@Nullable String myVar;
...                // myVar has type @Nullable String here.
myVar.hashCode(); // warning: possible dereference of null.
...
if (myVar != null) {
    ...            // myVar has type @NonNull String here.
    myVar.hashCode(); // no warning.
}
```

Here is another example. Note that the same expression may yield a warning or not depending on its context (that is, depending on the current type refinement).

```
@Nullable String myVar;
...                // myVar has type @Nullable String
myVar = "hello";
...                // myVar has type @NonNull String
myVar.hashCode(); // no warning
...
myVar = myMap.get(someKey);
...                // myVar has type @Nullable String
myVar.hashCode(); // warning: possible dereference of null
```

Type refinement applies to every checker, including new checkers that you write. Here is an example for the Regex Checker (Chapter 11, page 87):

```
void m2(@Unannotated String s) {
    s = RegexUtil.asRegex(s, 2); // asRegex throws an exception if its argument is not
                                // a regex with the given number of capturing groups
    ... // s now has type "@Regex(2) String"
}
```

27.7.2 Type refinement behavior

The checker treats a variable or expression as a subtype of its declared type:

- starting at the time that it is assigned a value, a method establishes a postcondition (e.g., as expressed by `@EnsuresNonNull` or `@EnsuresQualifierIf`), or a run-time check is performed (e.g., via an assertion or `if` statement).
- until its value might change (e.g., via an assignment, or because a method call might have a side effect).

The checker never treats a variable as a supertype of its declared type. For example, an expression with declared type `@NonNull` type is never treated as possibly-null, and such an assignment is always illegal.

The functionality has a variety of names: automatic type refinement, flow-sensitive type qualifier inference, local type inference, and sometimes just “flow”.

27.7.3 Which types are refined

You generally do not need to annotate the top-level type of a local variable. You do need to annotate its type arguments or array element types. (Type refinement does not change them, because doing so would not produce a subtype, as

explained in see Section 26.1.6 and Section 27.1.) Type refinement works within a method, so you still need to annotate method signatures (parameter and return type) and field types.

If you find examples where you think a value should be inferred to have (or not have) a given annotation, but the checker does not do so, please submit a bug report (see Section 35.2) that includes a small piece of Java code that reproduces the problem.

Fields and type refinement

Type refinement infers the type of fields in some restricted cases:

- A final initialized field: Type inference is performed for final fields that are initialized to a compile-time constant at the declaration site; so the type of `protocol` is `@NonNull String` in the following declaration:

```
public final String protocol = "https";
```

Such an inferred type may leak to the public interface of the class. If you wish to override such behavior, you can explicitly insert the desired annotation, e.g.,

```
public final @Nullable String protocol = "https";
```

- Within method bodies: Type inference is performed for fields in the context of method bodies, like local variables or any other expression. Consider the following example, where `updatedAt` is a nullable field:

```
class DBObject {
    @Nullable Date updatedAt;

    void m() {
        // updatedAt is @Nullable, so warning about .getTime()
        ... updatedAt.getTime() ... // warning about possible NullPointerException

        if (updatedAt == null) {
            updatedAt = new Date();
        }

        // updatedAt is now @NonNull, so .getTime() call is OK
        ... updatedAt.getTime() ...
    }
}
```

A method call may invalidate inferences about field types; see Section 27.7.5.

27.7.4 Run-time tests and type refinement

Some type systems support a run-time test that the Checker Framework can use to refine types within the scope of a conditional such as `if`, after an `assert` statement, etc.

Whether a type system supports such a run-time test depends on whether the type system is computing properties of data itself, or properties of provenance (the source of the data). An example of a property about data is whether a string is a regular expression. An example of a property about provenance is units of measure: there is no way to look at the representation of a number and determine whether it is intended to represent kilometers or miles.

Type systems that support a run-time test are:

- Nullness Checker for null pointer errors (see Chapter 3, page 27)
- Map Key Checker to track which values are keys in a map (see Chapter 4, page 48)
- Optional Checker for errors in using the `Optional` type (see Chapter 5, page 52)
- Lock Checker for concurrency and lock errors (see Chapter 7, page 59)
- Index Checker for array accesses (see Chapter 8, page 70)

- Regex Checker to prevent use of syntactically invalid regular expressions (see Chapter 11, page 87)
- Format String Checker to ensure that format strings have the right number and type of % directives (see Chapter 12, page 90)
- Internationalization Format String Checker to ensure that i18n format strings have the right number and type of {} directives (see Chapter 13, page 97)

Type systems that do not currently support a run-time test, but could do so with some additional implementation work, are

- Interning Checker for errors in equality testing and interning (see Chapter 6, page 54)
- Property File Checker to ensure that valid keys are used for property files and resource bundles (see Chapter 14, page 103)
- Internationalization Checker to ensure that code is properly internationalized (see Chapter 14.2, page 104)
- Signature String Checker to ensure that the string representation of a type is properly used, for example in `Class.forName` (see Chapter 15, page 106).
- Constant Value Checker to determine whether an expression's value can be known at compile time (see Chapter 21, page 127)

Type systems that cannot support a run-time test are:

- Initialization Checker to ensure all fields are set in the constructor (see Chapter 3.8, page 38)
- Fake Enum Checker to allow type-safe fake enum patterns and type aliases or typedefs (see Chapter 9, page 80)
- Tainting Checker for trust and security errors (see Chapter 10, page 84)
- GUI Effect Checker to ensure that non-GUI threads do not access the UI, which would crash the application (see Chapter 16, page 109)
- Units Checker to ensure operations are performed on correct units of measurement (see Chapter 17, page 114)
- Signedness Checker to ensure unsigned and signed values are not mixed (see Chapter 18, page 118)
- Aliasing Checker to identify whether expressions have aliases (see Chapter 19, page 121)
- Purity Checker to identify whether methods have side effects (see Chapter 19, page 121)
- Subtyping Checker for customized checking without writing any code (see Chapter 24, page 138)

27.7.5 Side effects, determinism, purity, and type refinement

Calling a method typically causes the checker to discard its knowledge of the refined type, because the method might assign a field. The `@SideEffectFree` annotation indicates that the method has no side effects, so calling it does not invalidate any dataflow facts.

Calling a method twice might have different results, so facts known about one call cannot be relied upon at another call. The `@Deterministic` annotation indicates that the method returns the same result every time it is called on the same arguments.

`@Pure` means both `@SideEffectFree` and `@Deterministic`. The `@TerminatesExecution` annotation indicates that a given method never returns. This can enable the type refinement to be more precise.

Chapter 20 gives more information about these annotations. This section explains how to use them to improve type refinement.

Side effects

Consider the following declarations and uses:

```
@Nullable Object myField;

int computeValue() { ... }

void m() {
```

```

...
if (myField != null) {
    // The type of myField is now "@NonNull Object".
    int result = computeValue();
    // The type of myField is now "@Nullable Object",
    // because computeValue might have set myField to null.
    myField.toString(); // Warning: possible null pointer exception.
}
}

```

There are three ways to express that `computeValue` does not set `myField` to null, and thus to prevent the Nullness Checker from issuing a warning about the call `myField.toString()`.

1. If `computeValue` has no side effects, declare it as

```

@SideEffectFree
int computeValue() { ... }

```

The Nullness Checker issues no warnings, because it can reason that the second occurrence of `myField` has the same (non-null) value as the one in the test.

2. If no method resets `myField` to null after it has been initialized to a non-null value (even if a method has some other side effect), declare `myField` as `@MonotonicNonNull`.

```

@MonotonicNonNull Object myField;

```

3. If `computeValue` sets `myField` to a non-null value, declare it as

```

@EnsuresNonNull("myField")
int computeValue() { ... }

```

If `computeValue` maintains `myField` as a non-null value, even if it might have other side effects and even if other methods might set `myField` to null, declare it as

```

@RequiresNonNull("myField")
@EnsuresNonNull("myField")
int computeValue() { ... }

```

Deterministic methods

Consider the following declaration and uses:

```

@Nullable Object getField(Object arg) { ... }

void m() {
    ...
    if (x.getField(y) != null) {
        x.getField(y).toString(); // warning: possible null pointer exception
    }
}

```

The Nullness Checker issues a warning regarding the `toString()` call, because its receiver `x.getField(y)` might be null, according to the `@Nullable` return type in the declaration of `getField`. The Nullness Checker cannot assume that `getField` returns non-null on the second call, just based on the fact that it returned non-null on the first call.

To indicate that a method returns the same value each time it is called on the same arguments, use the `@Deterministic` annotation. Actually, it is necessary to use `@Pure` which means both `@Deterministic` and `@SideEffectFree`, because otherwise the first call might change a value that the method depends on.

If you change the declaration of `getField` to

```
@Pure
@Nullable Object getField(Object arg) { ... }
```

then the Nullness Checker issues no warnings. Because `getField` is `@SideEffectFree`, the values of `x` and `y` are the same at both invocations. Because `getField` is `@Deterministic`, the two invocations of `x.getField(y)` have the same value. Therefore, `x.getField(y)` is non-null within the `then` branch of the `if` statement.

27.7.6 Assertions

If your code contains an `assert` statement, then your code could behave in two different ways at run time, depending on whether assertions are enabled or disabled via the `-ea` or `-da` command-line options to `java`.

By default, the Checker Framework outputs warnings about any error that could happen at run time, whether assertions are enabled or disabled.

If you supply the `-AassumeAssertionsAreEnabled` command-line option, then the Checker Framework assumes assertions are enabled. If you supply the `-AassumeAssertionsAreDisabled` command-line option, then the Checker Framework assumes assertions are disabled. You may not supply both command-line options. It is uncommon to supply either one.

These command-line arguments have no effect on processing of `assert` statements whose message contains the text `@AssumeAssertion`; see Section 28.2.

27.8 Writing Java expressions as annotation arguments

Sometimes, it is necessary to write a Java expression as the argument to an annotation. The annotations that take a Java expression as an argument include:

- `@RequiresQualifier`
- `@EnsuresQualifier`
- `@EnsuresQualifierIf`
- `@RequiresNonNull`
- `@EnsuresNonNull`
- `@EnsuresNonNullIf`
- `@KeyFor`
- `@EnsuresKeyFor`
- `@EnsuresKeyForIf`
- `@I18nFormatFor`
- `@EnsuresLockHeld`
- `@EnsuresLockHeldIf`
- `@GuardedBy`
- `@Holding`

The set of permitted expressions is a subset of all Java expressions:

- the receiver object, `this`. You can write `this` to annotate any variable or declaration where you could write `this` in code. Notably, it cannot be used in annotations on declarations of static fields or methods. For a field, `this` is the field's receiver, i.e. its container. For a local variable, it is the method's receiver.
- the receiver object as seen from the superclass, `super`. This can be used to refer to fields shadowed in the subclass (although shadowing fields is discouraged in Java).
- `<self>`, i.e. the value of the annotated reference (non-primitive) variable. Currently only defined for the `@GuardedBy` type system. For example, `@GuardedBy("<self>") Object o` indicates that the value referenced by `o` is guarded by the intrinsic (monitor) lock of the value referenced by `o`.

- a formal parameter, represented as # followed by the **one-based** parameter index. For example: #1, #3. It is not permitted to write #0 to refer to the receiver object; use `this` instead.

The formal parameter syntax #1 is less natural in source code than writing the formal parameter name. This syntax is necessary for separate compilation, when an annotated method has already been compiled into a `.class` file and a client of that method is later compiled. In the `.class` file, no formal parameter name information is available, so it is necessary to use a number to indicate a formal parameter. If all your annotated code is always provided to the checker in source code format (this also implies that you will never provide `.class` files to clients who might want to do type-checking), then you can use the formal parameter name instead of the numeric index.

- a local variable. Write the variable name. For example: `myLocalVar`. The variable must be in scope; for example, a method annotation on method `m` cannot mention a local variable that is declared inside `m`.
- a static variable. Write the class name and the variable, as in `System.out`.
- a field of any expression. For example: `next`, `this.next`, `#1.next`. You may optionally omit a leading “`this.`”, just as in Java. Thus, `this.next` and `next` are equivalent.
- an array access. For example: `this.myArray[i]`, `vals[#1]`.
- an array creation. For example: `new int[10]`, `new String[] "a", "b"`.
- literals: string, integer, char, long, float, double, null, class literals.
- a method invocation on any expression. This even works for overloaded methods and methods with type parameters. For example: `m1(x, y.z, #2)`, `a.m2("hello")`.

Currently, the Checker Framework cannot prove all contracts about method calls, so you may need to suppress some warnings.

One unusual feature of the Checker Framework’s Java expressions is that a method call is allowed to have side effects. Other tools forbid methods with side effects (and doing so is necessary if a specification is going to be checked at run time via assertions). The Checker Framework enables you to state more facts. For example, consider the annotation on `java.io.BufferedReader.ready()`:

```
@EnsuresNonNullIf(expression="readLine()", result=true)
@Pure public boolean ready() throws IOException { ... }
```

This states that if `readLine()` is called immediately after `ready()` returns true, then `readLine()` returns a non-null value.

Limitations: The following Java expressions may not currently be written:

- String concatenation expressions.
- Mathematical operators (plus, minus, division, ...).
- Comparisons (equality, less than, etc.).

Additionally, it is not possible to write quantification over all array components (e.g. to express that all array elements are non-null). There is no such Java expression, but it would be useful when writing specifications.

27.9 Field invariants

Sometimes a field declared in a superclass has a more precise type in a subclass. To express this fact, write `@FieldInvariant` on the subclass. It specifies the field’s type in the class on which this annotation is written. The field must be declared in a superclass and must be final.

For example,

```
class Person {
    final @Nullable String nickname;
    public Person(@Nullable String nickname) {
        this.nickname = nickname;
    }
}
```

```

// A rapper always has a nickname.
@FieldInvariant(qualifier = NonNull.class, field = "nickname")
class Rapper extends Person {
    public Rapper(String nickname) {
        super(nickname);
    }
    void method() {
        ... nickname.length() ... // legal, nickname is non-null in this class.
    }
}

```

A field invariant annotation can refer to more than one field. For example, `@FieldInvariant(qualifier = NonNull.class, field = {fieldA, fieldB})` means that `fieldA` and `fieldB` are both non-null in the class upon which the annotation is written. A field invariant annotation can also apply different qualifiers to different fields. For example, `@FieldInvariant(qualifier = {NonNull.class, Untainted.class}, field = {fieldA, fieldB})` means that `fieldA` is non-null and `fieldB` is untainted.

This annotation is inherited: if a superclass is annotated with `@FieldInvariant`, its subclasses have the same annotation. If a subclass has its own `@FieldInvariant`, then it must include the fields in the superclass annotation and those fields' annotations must be a subtype (or equal) to the annotations for those fields in the superclass `@FieldInvariant`.

Currently, the `@FieldInvariant` annotation is trusted rather than checked. In other words, the `@FieldInvariant` annotation introduces a loophole in the type system, which requires verification by other means such as manual examination.

27.10 Unused fields

In an inheritance hierarchy, subclasses often introduce new methods and fields. For example, a `Marsupial` (and its subclasses such as `Kangaroo`) might have a variable `pouchSize` indicating the size of the animal's pouch. The field does not exist in superclasses such as `Mammal` and `Animal`, so Java issues a compile-time error if a program tries to access `myMammal.pouchSize`.

If you cannot use subtypes in your program, you can enforce similar requirements using type qualifiers. For fields, use the `@Unused` annotation (Section 27.10.1), which enforces that a field or method may only be accessed from a receiver expression with a given annotation (or one of its subtypes). For methods, annotate the receiver parameter `this`; then a method call type-checks only if the actual receiver is of the specified type.

Also see the discussion of `typestate` checkers, in Chapter 25.17.

27.10.1 @Unused annotation

A Java subtype can have more fields than its supertype. For example:

```

class Animal {}
class Mammal extends Animal { ... }
class Marsupial extends Mammal {
    int pouchSize; // pouch capacity, in cubic centimeters
    ...
}

```

You can simulate the same effect for type qualifiers: the `@Unused` annotation on a field declares that the field may *not* be accessed via a receiver of the given qualified type (or any *supertype*). For example:

```

class Animal {
    @Unused(when=Mammal.class)
    int pouchSize; // pouch capacity, in cubic centimeters
}

```

```
...
}
@interface Mammal {}
@interface Marsupial {}

@Marsupial Animal joey = ...;
... joey.pouchSize ... // OK
@Mammal Animal mae = ...;
... mae.pouchSize ... // compile-time error
```

The above class declaration is like writing

```
class @Mammal-Animal { ... }
class @Marsupial-Animal {
    int pouchSize; // pouch capacity, in cubic centimeters
    ...
}
```

Chapter 28

Suppressing warnings

When the Checker Framework reports a warning, it's best to fix the underlying problem, by changing the code or its annotations. For each warning, follow the methodology in Section 2.4.5 to correct the underlying problem.

This section describes what to do if the methodology of Section 2.4.5 indicates that you need to suppress the warning. You won't change your code, but you will prevent the Checker Framework from reporting this particular warning to you. (Changing the code to fix a bug is another way to prevent the Checker Framework from issuing a warning, but it is not what this chapter is about.)

You may wish to suppress checker warnings because of unannotated libraries or un-annotated portions of your own code, because of application invariants that are beyond the capabilities of the type system, because of checker limitations, because you are interested in only some of the guarantees provided by a checker, or for other reasons. Suppressing a warning is similar to writing a cast in a Java program: the programmer knows more about the type than the type system does and uses the warning suppression or cast to convey that information to the type system.

You can suppress a warning message in a single variable initializer, method, or class by using the following mechanisms:

- the `@SuppressWarnings` annotation (Section 28.1), or
- the `@AssumeAssertion` string in an `assert` message (Section 28.2).

You can suppress warnings throughout the codebase by using the following mechanisms:

- the `-AsuppressWarnings` command-line option (Section 28.3),
- the `-AskipUses` and `-AonlyUses` command-line options (Section 28.4),
- the `-AskipDefs` and `-AonlyDefs` command-line options (Section 28.5),
- the `-AuseConservativeDefaultsForUncheckedCode=source` command-line option (Section 31.4),
- the `-Alint` command-line option enables/disables optional checks (Section 28.6), or
- not running the annotation processor (Section 28.7).

Some type checkers can suppress warnings via

- checker-specific mechanisms (Section 28.8).

The rest of this chapter explains these mechanisms in turn.

You can use the `-AwarnUnneededSuppressions` command-line option to issue a warning if a `@SuppressWarnings` did not suppress any warnings issued by the current checker.

28.1 `@SuppressWarnings` annotation

You can suppress specific errors and warnings by use of the `@SuppressWarnings` annotation, for example `@SuppressWarnings("interning")` or `@SuppressWarnings("nullness")`. Section 28.1.1 explains the syntax of the argument string.

A `@SuppressWarnings` annotation may be placed on program declarations such as a local variable declaration, a method, or a class. It suppresses all warnings within that program element. Section 28.1.2 discusses where the annotation may be written in source code.

Section 28.1.3 gives best practices for writing `@SuppressWarnings` annotations.

28.1.1 `@SuppressWarnings` syntax

The `@SuppressWarnings` annotation takes a string argument, in one of the following forms: `"checkername:messagekey"`, `"checkername"`, or `"messagekey"`.

The argument `checkername` is in lower case and is derived from the way you invoke the checker. For example, if you invoke a checker as `javac -processor MyNiftyChecker ...`, then you would suppress its error messages with `@SuppressWarnings("mynifty")`. (An exception is the Subtyping Checker, for which you use the annotation name; see Section 24.1.) Sometimes, a checker honors `checkername` arguments; use the `-AshowSuppressWarningsKeys` command-line option to see them. Using "all" as the `checkername` applies to all checkers; this is not recommended, except for messages common to all checkers such as purity-related messages when using `-AcheckPurityAnnotations`.

The argument `messagekey` is the message key for the error. Each warning message from the compiler gives the most specific suppression key that can be used to suppress that warning. An example is `dereference.of.nullable` in

```
MyFile.java:107: error: [dereference.of.nullable] dereference of possibly-null reference myList
    myList.add(elt);
    ^
```

You are allowed to use any substring of a message key, so long as the substring extends at each end to a period or an end of the key. For example, to suppress a warning with message key `"assignment.type.incompatible"`, you could use `@SuppressWarnings("assignment")`, `@SuppressWarnings("assignment.type")`, `@SuppressWarnings("type.incompatible")` or other variants. We recommend using the longest possible message key; a short message might suppress more warnings than you expect.

If the `checkername` part is omitted, the `@SuppressWarnings` applies to all checkers. If the `messagekey` part is omitted, the `@SuppressWarnings` applies to all messages (it suppresses all warnings from the given checker).

With the `-ArequirePrefixInWarningSuppressions` command-line option, a warning is only suppressed if the key is in the `"checkername"` or `"checkername:messagekey"` format, as in `@SuppressWarnings("nullness")` or `@SuppressWarnings("nullness:assignment.type.incompatible")`.

28.1.2 Where `@SuppressWarnings` can be written

`@SuppressWarnings` is a declaration annotation, so it may be placed on program declarations such as a local variable declaration, a method, or a class. It cannot be used on statements, expressions, or types. (`assert` plus `@AssumeAssertion` can be used between statements and can affect arbitrary expressions; see Section 28.2.)

Always write a `@SuppressWarnings` annotation on the smallest possible scope. To reduce the scope of a `@SuppressWarnings` annotation, it is sometimes desirable to refactor the code. You might extract an expression into a local variable, so that warnings can be suppressed just for that local variable's initializer expression. Likewise, you might extract some code into a separate method, so that warnings can be suppressed just for its body. Or, you can use `@AssumeAssertion` on an `assert` statement; see Section 28.2.

As an example, consider suppressing a warning at an assignment that you know is safe. Here is an example that uses the Tainting Checker (Section 10). Assume that `expr` has compile-time (declared) type `@Tainted String`, but you know that the run-time value of `expr` is untainted.

```
@SuppressWarnings("tainting:cast.unsafe") // expr is untainted because ... [explanation goes here]
@Untainted String myvar = expr;
```

Java does not permit annotations (such as `@SuppressWarnings`) on assignments (or on other statements or expressions), so it would have been *illegal* to write

```
@Untainted String myvar;
...
@SuppressWarnings("tainting:cast.unsafe") // expr is untainted because ...
myvar = expr;
```

28.1.3 Good practices when suppressing warnings

Suppress warnings in the smallest possible scope

Prefer `@SuppressWarnings` on a local variable to one on a method, and prefer one on a method to one on a class.

You may be able to suppress a warning about a use of an expression by writing `@AssumeAssertion` for the expression, before the use. See Section 28.2.

Another way to reduce the scope of a `@SuppressWarnings` is to extract the expression into a new local variable and place a `@SuppressWarnings` annotation on the variable declaration. See Section 28.1.2.

Use a specific argument to `@SuppressWarnings`

It is best to use the most specific possible message key to suppress just a specific error that you know to be a false positive. The checker outputs this message key when it issues an error. If you use a broader `@SuppressWarnings` annotation, then it may mask other errors that you needed to know about.

Any of the following would have suppressed the warning in Section 28.1.2:

```
@SuppressWarnings("tainting")           // suppresses all tainting-related warnings
@SuppressWarnings("cast")             // suppresses warnings from all checkers about casts
@SuppressWarnings("unsafe")          // suppresses warnings from all checkers about unsafe code
@SuppressWarnings("cast.unsafe")     // suppresses warnings from all checkers about unsafe casts
@SuppressWarnings("tainting:cast")   // suppresses tainting warnings about casts
@SuppressWarnings("tainting:unsafe") // suppresses tainting warnings about unsafe code
@SuppressWarnings("tainting:cast.unsafe") // suppresses tainting warnings about unsafe casts
```

The last one is the most specific, and therefore is the best style.

Justify why the warning is a false positive

A `@SuppressWarnings` annotation asserts that the programmer knows that the code is actually correct or safe (that is, no undesired behavior will occur), even though the type system is unable to prove that the code is correct or safe.

Whenever you write a `@SuppressWarnings` annotation, you should also write, typically on the same line, a code comment explaining why the code is actually correct. In some cases you might also justify why the code cannot be rewritten in a simpler way that would be amenable to type-checking. Also make it clear what error is being suppressed. (This is particularly important when the `@SuppressWarnings` is on a method declaration and the suppressed warning might be anywhere in the method body.)

This documentation will help you and others to understand the reason for the `@SuppressWarnings` annotation. It will also help you audit your code to verify all the warning suppressions. (The code is correct only if the checker issues no warnings *and* each `@SuppressWarnings` is correct.)

A suppression message like “a.f is not null” is not useful. The fact that you are suppressing the warning means that you believe that a.f is not null. The message should explain *why* you believe that; for example, “a.f was checked above and no subsequent side effect can affect it”.

Here are some terse examples from libraries in plume-lib:

```
@SuppressWarnings("cast") // cast is redundant (except when checking nullness)
@SuppressWarnings("interning") // FbType.FREE is interned but is not annotated
@SuppressWarnings("interning") // equality testing optimization
@SuppressWarnings("nullness") // used portion of array is non-null
@SuppressWarnings("nullness") // oi.factory is a static method, so null first argument is OK
@SuppressWarnings("purity") // side effect to local state of type BitSet
```

A particularly good (and concise) justification is to reference an issue in the issue tracker, as in these two from Daikon:

```
@SuppressWarnings("flowexpr.parse.error") // https://tinyurl.com/cfissue/862
@SuppressWarnings("keyfor") // https://tinyurl.com/cfissue/877
```

Please report false positive warnings, then reference them in your warning suppressions. This permits the Checker Framework maintainers to know about the problem, it helps them with prioritization (by knowing how often in your codebase a particular issue arises), and it enables you to know when an issue has been fixed (though the `-AwarnUnneededSuppressions` command-line option also serves the latter purpose).

28.2 @AssumeAssertion string in an assert message

You can suppress a warning by asserting that some property is true, and placing the string `@AssumeAssertion(warningkey)` in the assertion message.

For example, in this code:

```
while (c != Object.class) {
    ...
    c = c.getSuperclass();
    assert c != null
        : "@AssumeAssertion(nullness): c was not Object, so its superclass is not null";
}
```

the Nullness Checker assumes that `c` is non-null from the `assert` statement forward (including on the next iteration through the loop).

The `assert` expression must be an expression that would affect flow-sensitive type refinement (Section 27.7), if the expression appeared in a conditional test. Each type system has its own rules about what type refinement it performs.

The warning key is exactly as in the `@SuppressWarnings` annotation (Section 28.1). The same good practices apply as for `@SuppressWarnings` annotations, such as writing a comment justifying why the assumption is safe (Section 28.1.3). Sometimes, writing an assertion and `@AssumeAssertion` is a less disruptive code change than refactoring to create a location where `@SuppressWarnings` can be written.

The `-AassumeAssertionsAreEnabled` and `-AassumeAssertionsAreDisabled` command-line options (Section 27.7.6) do not affect processing of `assert` statements that have `@AssumeAssertion` in their message. Writing `@AssumeAssertion` means that the assertion would succeed if it were executed, and the Checker Framework makes use of that information regardless of the `-AassumeAssertionsAreEnabled` and `-AassumeAssertionsAreDisabled` command-line options.

28.2.1 Suppressing warnings and defensive programming

This section explains the distinction between two different uses for assertions (and for related methods like `JUnit's Assert.assertNotNull`).

Assertions are commonly used for two distinct purposes: documenting how the program works and debugging the program when it does not work correctly. By default, the Checker Framework assumes that each assertion is used for debugging: the assertion might fail at run time, and the programmer wishes to be informed at compile time about such possible run-time errors. On the other hand, if you write the `@AssumeAssertion` string in the `assert` message, then the Checker Framework assumes that you have used some other technique to verify that the assertion can never fail at run time, so the checker assumes the assertion passes and does not issue a warning.

Distinguishing the purpose of each assertion is important for precise type-checking. Suppose that a programmer encounters a failing test, adds an assertion to aid debugging, and fixes the test. The programmer leaves the assertion in the program if the programmer is worried that the program might fail in a similar way in the future. The Checker Framework should not assume that the assertion succeeds — doing so would defeat the very purpose of the Checker Framework, which is to detect errors at compile time and prevent them from occurring at run time.

On the other hand, assertions sometimes document facts that a programmer has independently verified to be true, and the Checker Framework can leverage these assertions in order to avoid issuing false positive warnings. The programmer

marks such assertions with the `@AssumeAssertion` string in the `assert` message. Only do so if you are sure that the assertion always succeeds at run time.

Sometimes methods such as `NullnessUtil.castNonNull` are used instead of assertions. Just as for assertions, you can treat them as debugging aids or as documentation. If you know that a particular codebase uses a nullness-checking method not for defensive programming but to indicate facts that are guaranteed to be true (that is, these assertions will never fail at run time), then you can suppress warnings related to it. Annotate its definition just as `NullnessUtil.castNonNull` is annotated (see the source code for the Checker Framework). Also, be sure to document the intention in the method's Javadoc, so that programmers do not accidentally misuse it for defensive programming.

If you are annotating a codebase that already contains precondition checks, such as:

```
public String get(String key, String def) {
    checkNotNull(key, "key"); // NOI18N
    ...
}
```

then you should mark the appropriate parameter as `@NonNull` (which is the default). This will prevent the checker from issuing a warning about the `checkNotNull` call.

28.3 `-AsuppressWarnings` command-line option

Supplying the `-AsuppressWarnings` command-line option is equivalent to writing a `@SuppressWarnings` annotation on every class that the compiler type-checks. The argument to `-AsuppressWarnings` is a comma-separated list of warning suppression keys, as in `-AsuppressWarnings=purity,uninitialized`.

When possible, it is better to write a `@SuppressWarnings` annotation with a smaller scope, rather than using the `-AsuppressWarnings` command-line option.

28.4 `-AskipUses` and `-AonlyUses` command-line options

You can suppress all errors and warnings at all *uses* of a given class, or suppress all errors and warnings except those at uses of a given class. (The class itself is still type-checked, unless you also use the `-AskipDefs` or `-AonlyDefs` command-line option, see 28.5).

Set the `-AskipUses` command-line option to a regular expression that matches class names (not file names) for which warnings and errors should be suppressed. Or, set the `-AonlyUses` command-line option to a regular expression that matches class names (not file names) for which warnings and errors should be emitted; warnings about uses of all other classes will be suppressed.

For example, suppose that you use `"-AskipUses=^java\."` on the command line (with appropriate quoting) when invoking `javac`. Then the checkers will suppress all warnings related to classes whose fully-qualified name starts with `java.`, such as all warnings relating to invalid arguments and all warnings relating to incorrect use of the return value.

To suppress all errors and warnings related to multiple classes, you can use the regular expression alternative operator `"|"`, as in `"-AskipUses="java\.lang\.|java\.util\."` to suppress all warnings related to uses of classes that belong to the `java.lang` or `java.util` packages. (Depending on your shell or other tool, you might need to change or remove the quoting.)

You can supply both `-AskipUses` and `-AonlyUses`, in which case the `-AskipUses` argument takes precedence, and `-AonlyUses` does further filtering but does not add anything that `-AskipUses` removed.

Warning: Use the `-AonlyUses` command-line option with care, because it can have unexpected results. For example, if the given regular expression does not match classes in the JDK, then the Checker Framework will suppress every warning that involves a JDK class such as `Object` or `String`. The meaning of `-AonlyUses` may be refined in the future. Oftentimes `-AskipUses` is more useful.

28.5 `-AskipDefs` and `-AonlyDefs` command-line options

You can suppress all errors and warnings in the *definition* of a given class, or suppress all errors and warnings except those in the definition of a given class. (Uses of the class are still type-checked, unless you also use the `-AskipUses` or `-AonlyUses` command-line option, see 28.4.)

Set the `-AskipDefs` command-line option to a regular expression that matches class names (not file names) in whose definition warnings and errors should be suppressed. Or, set the `-AonlyDefs` command-line option to a regular expression that matches class names (not file names) whose definitions should be type-checked.

For example, if you use `"-AskipDefs=^mypackage\."` on the command line (with appropriate quoting) when invoking `javac`, then the definitions of classes whose fully-qualified name starts with `mypackage.` will not be checked.

If you supply both `-AskipDefs` and `-AonlyDefs`, then `-AskipDefs` takes precedence.

Another way not to type-check a file is not to pass it on the compiler command-line: the Checker Framework type-checks only files that are passed to the compiler on the command line, and does not type-check any file that is not passed to the compiler. The `-AskipDefs` and `-AonlyDefs` command-line options are intended for situations in which the build system is hard to understand or change. In such a situation, a programmer may find it easier to supply an extra command-line argument, than to change the set of files that is compiled.

A common scenario for using the arguments is when you are starting out by type-checking only part of a legacy codebase. After you have verified the most important parts, you can incrementally check more classes until you are type-checking the whole thing.

28.6 `-Alint` command-line option

The `-Alint` option enables or disables optional checks, analogously to `javac`'s `-Xlint` option. Each of the distributed checkers supports at least the following lint options (and possibly more, see the checker's documentation):

- `cast:unsafe` (default: on) warn about unsafe casts that are not checked at run time, as in `((@NonNull String) myref)`. Such casts are generally not necessary because of type refinement (Section 27.7).
- `cast:redundant` (default: on) warn about redundant casts that are guaranteed to succeed at run time, as in `((@NonNull String) "m")`. Such casts are not necessary, because the target expression of the cast already has the given type qualifier.
- `cast` Enable or disable all cast-related warnings.
- `all` Enable or disable all lint warnings, including checker-specific ones if any. Examples include `redundantNullComparison` for the Nullness Checker (see Section 2) and `dotequals` for the Interning Checker (see Section 6.4). This option does not enable/disable the checker's standard checks, just its optional ones.
- `none` The inverse of `all`: disable or enable all lint warnings, including checker-specific ones if any.

To activate a lint option, write `-Alint=` followed by a comma-delimited list of check names. If the option is preceded by a hyphen (`-`), the warning is disabled. For example, to disable all lint options except redundant casts, you can pass `-Alint=-all,cast:redundant` on the command line.

Only the last `-Alint` option is used; all previous `-Alint` options are silently ignored. In particular, this means that `-Alint=all -Alint=cast:redundant` is *not* equivalent to `-Alint=-all,cast:redundant`.

28.7 Don't run the processor

You can compile parts of your code without use of the `-processor` switch to `javac`. No checking is done during such compilations, so no warnings are issued related to pluggable type-checking.

You can direct your build system to avoid compiling certain parts of your code. For example, the `-Dmaven.test.skip=true` command-line argument tells Maven not to compile (or run) the tests.

28.8 Checker-specific mechanisms

Finally, some checkers have special rules. For example, the Nullness checker (Chapter 3) uses the special `castNonNull` method to suppress warnings (Section 3.4.1). This manual also explains special mechanisms for suppressing warnings issued by the Fenum Checker (Section 9.4) and the Units Checker (Section 17.5).

Chapter 29

Handling legacy code

Section 2.4.2 describes a methodology for applying annotations to legacy code. This chapter tells you what to do if, for some reason, you cannot change your code in such a way as to eliminate a checker warning.

Also recall that you can convert checker errors into warnings via the `-Awarns` command-line option; see Section 2.2.2.

29.1 Checking partially-annotated programs: handling unannotated code

Sometimes, you wish to type-check only part of your program. You might focus on the most mission-critical or error-prone part of your code. When you start to use a checker, you may not wish to annotate your entire program right away. You may not have enough knowledge to annotate poorly-documented libraries that your program uses.

If annotated code uses unannotated code, then the checker may issue warnings. For example, the Nullness Checker (Chapter 3) will warn whenever an unannotated method result is used in a non-null context:

```
@NonNull myvar = unannotated_method(); // WARNING: unannotated_method may return null
```

If the call *can* return null, you should fix the bug in your program by removing the `@NonNull` annotation in your own program.

If the library call *never* returns null, there are several ways to eliminate the compiler warnings.

1. Annotate `unannotated_method` in full. This approach provides the strongest guarantees, but may require you to annotate additional methods that `unannotated_method` calls. See Chapter 31 for a discussion of how to annotate libraries for which you have no source code.
2. Annotate only the signature of `unannotated_method`, and suppress warnings in its body. Two ways to suppress the warnings are via a `@SuppressWarnings` annotation or by not running the checker on that file (see Chapter 28).
3. Suppress all warnings related to uses of `unannotated_method` via the `skipUses` processor option (see Section 28.4). Since this can suppress more warnings than you may expect, it is usually better to annotate at least the method's signature. If you choose the boundary between the annotated and unannotated code wisely, then you only have to annotate the signatures of a limited number of classes/methods (e.g., the public interface to a library or package).

Chapter 31 discusses adding annotations to signatures when you do not have source code available. Chapter 28 discusses suppressing warnings.

29.1.1 Declaration annotations

When a declaration annotation is an alias for a type annotation, then the Checker Framework may move the annotation before replacing it by the canonical version. (If the declaration annotation is in an `org.checkerframework` package, it is not moved.)

For example,

```
import android.support.annotation.NonNull;
...
@NonNull Object [] returnsArray();
```

is treated as if the programmer had written

```
import org.checkerframework.checker.nullness.qual.NonNull;
...
Object @NonNull [] returnsArray();
```

because Android's `@NonNull` annotation is a declaration annotation, which is understood to apply to the top-level return type of the annotated method.

When possible, you should use type annotations rather than declaration annotations.

Users who are using old Java 5–7 declaration annotations (for instance, from the no-longer-supported FindBugs tool) can use annotations in package `org.checkerframework.checker.nullness.compatqual` to avoid name conflicts. These are available in package `checker-compat-qual` on Maven Central. Once the users are ready to upgrade to Java 8+ type annotations, those compatibility annotations are no longer necessary.

Chapter 30

Type inference

There are two different tasks that are commonly called “type inference”:

1. Type inference during type-checking: The type-checker fills in an appropriate type where the programmer didn't write one, but does not change the source code. See Section 30.1.
2. Type inference to annotate a program: As a separate step before type-checking, a type inference tool inserts type qualifiers into the source code. See Section 30.2.

Each variety has its own advantages, discussed below. Advantages of *all* varieties of type inference include:

- Less work for the programmer.
- The tool chooses the most general type, whereas a programmer might accidentally write a more-specific, less-generally-useful annotation.

30.1 Local type inference during type-checking

During type-checking, if certain variables have no programmer-written type qualifier, the type-checker determines whether there is some type qualifier that would permit the program to type-check. If so, the type-checker uses that type qualifier, but does not change the source code. Each time the type-checker runs, it re-infers the type qualifier for that variable. If no type qualifier exists that permits the program to type-check, the type-checker issues a warning.

Local type inference is built into the Checker Framework. Every checker automatically uses it. As a result, a programmer typically does not have to write any qualifiers inside the body of a method (except occasionally on type arguments). However, it primarily works within a method, not across method boundaries. The source code must already contain annotations for method signatures (arguments and return values) and fields.

Advantages of this variety of type inference include:

- If the type qualifier is obvious to the programmer, then omitting it can reduce annotation clutter in the program.
- If the code changes, then there is no old annotation that might need to be updated.
- Within-method type inference occurs automatically. The programmer doesn't have to do anything to take advantage of it.

For more details about local type inference during type-checking, also known as “flow-sensitive type refinement”, see Section 27.7.

30.2 Type inference to annotate a program

As a separate step before type-checking, a type inference tool takes the program as input, and outputs a set of type qualifiers that would make the program type-check. (If no such set exists, for example because the program is not

type-correct, then the inference tool does its best but makes no guarantees.) These qualifiers are inserted into the source code or the class file. They can be viewed and adjusted by the programmer, and can be used by tools such as the type-checker.

Advantages of this variety of type inference include:

- The inference may be more precise by taking account of the entire program rather than just reasoning one method at a time.
- The program source code contains documentation in the form of type qualifiers, which can aid programmer understanding and may make type-checking warnings more comprehensible.

30.2.1 Type inference tools

This section lists tools that take a program and output a set of annotations for it. It first lists tools that work only for a single type system (but may do a more accurate job for that type system) then lists general tools that work for any type system.

Type inference for specific type systems

Section 3.3.8 lists several tools that infer annotations for the Nullness Checker.

If you run the Checker Framework with the `-AsuggestPureMethods` command-line option, it will suggest methods that can be marked as `@SideEffectFree`, `@Deterministic`, or `@Pure`; see Section 27.7.5.

Type inference for any type system

By supplying the `-Ainfer` command-line option, any type-checker can infer annotations. See Section 30.3.

Cascade [VPEJ14] is an Eclipse plugin that implements interactive type qualifier inference. Cascade is interactive rather than fully-automated: it makes it easier for a developer to insert annotations. Cascade starts with an unannotated program and runs a type-checker. For each warning it suggests multiple fixes, the developer chooses a fix, and Cascade applies it. Cascade works with any checker built on the Checker Framework. You can find installation instructions and a video tutorial at <https://github.com/reprogrammer/cascade>.

30.3 Whole-program inference

Whole-program inference is an interprocedural inference that infers types for fields, method parameters, and method return types that do not have a user-written qualifier (for the given type system). The inferred type qualifiers are inserted into your program. The inferred type is the most specific type that is compatible with all the uses in the program. For example, the inferred type for a field is the least upper bound of the types of all the expressions that are assigned into the field.

To use whole-program inference, make sure that `insert-annotations-to-source`, from the Annotation File Utilities project, is on your path (for example, its directory is in the `$PATH` environment variable). Then, run the script `checker-framework/checker/bin/infer-and-annotate.sh`. Its command-line arguments are:

1. Optional: Command-line arguments to `insert-annotations-to-source`.
2. Processor's name.
3. Target program's classpath. This argument is required; pass "" if it is empty.
4. Optional: Extra processor arguments which will be passed to the checker, if any. You may supply any number of such arguments, or none. Each such argument must start with a hyphen.
5. Optional: Paths to `.jaif` files used as input in the inference process.
6. Paths to `.java` files in the program.

For example, to add annotations to the `plume-lib` project:

```

git clone https://github.com/mernst/plume-lib.git
cd plume-lib
make jar
$CHECKERFRAMEWORK/checker/bin/infer-and-annotate.sh \
    "LockChecker,NullnessChecker" java/plume.jar:java/lib/junit-4.12.jar:$JAVA_HOME/lib/tools.jar \
    `find java/src/plume/ -name "*.java"`
# View the results
git diff

```

You may need to wait a few minutes for the command to complete. You can ignore warnings that the command outputs while it tries different annotations in your code.

It is recommended that you run `infer-and-annotate.sh` on a copy of your code, so that you can see what changes it made and so that it does not change your only copy. One way to do this is to work in a clone of your repository that has no uncommitted changes.

Whole-program inference differs from type refinement (Section 27.7) in three ways. First, type refinement only works within a method body. Second, type refinement always refines the current type, regardless of whether the value already has an annotation in the source code. Third, whole-program inference can infer a subtype or a supertype of the default type, by contrast with type refinement which always refines the current type to a subtype.

30.3.1 Whole-program inference ignores some code

Whole-program inference ignores code within the scope of a `@SuppressWarnings` annotation with an appropriate key (Section 28.1). In particular, uses within the scope do not contribute to the inferred type, and declarations within the scope are not changed. You should remove `@SuppressWarnings` annotations from the class declaration of any class you wish to infer types for.

As noted below, whole-program inference requires invocations of your code, or assignments to your methods, to generalize from. If a field is set via reflection (such as via injection), then whole-program inference would produce an inaccurate result. There are two ways to make whole-program inference ignore such a field. (1) You probably have an annotation such as `@Inject` or `@Option` that indicates such fields. Meta-annotate the declaration of the `Inject` or `Option` annotation with `@IgnoreInWholeProgramInference`. (2) Annotate the field to be ignored with `@IgnoreInWholeProgramInference`.

Whole-program inference, for a type-checker other than the Nullness Checker, ignores (pseudo-)assignments where the right-hand-side is the `null` literal.

30.3.2 Manually checking whole-program inference results

As with any type inference tool, it is a good idea to manually examine the results.

- Whole-program inference can produce undesired results when your code has non-representative or erroneous calls to a particular method or assignments to a particular field, as explained below. This is especially noticeable when the arguments or assignments are literals.
- If an annotation is inferred for a *use* of type variables; it might be more appropriate for you to move those annotations to the corresponding upper bounds of the type variable *declaration*.

Poor whole-program inference results due to non-representative uses

Whole-program inference determines a method parameter's type annotation based on what arguments are passed to the method, but not on how the parameter is used within the method body.

- If the program contains erroneous calls, the inferred annotations may reflect those errors. Suppose you intend method `m2` to be called with non-null arguments, but your program contains an error and one of the calls to `m2` passes `null` as the argument. Then the tool will infer that `m2`'s parameter has `@Nullable` type. You should correct the bug and re-run inference.

- If the program uses (say) a method in a limited way, then the inferred annotations will be legal for the program as currently written but may not be as general as possible and may not accommodate future program changes.

Here are some examples:

- Suppose that your program currently calls method `m1` only with non-null arguments. The tool will infer that `m1`'s parameter has `@NonNull` type. If you had intended the method to be able to take `null` as an argument and you later add such a call, the type-checker will issue a warning because the automatically-inserted `@NonNull` annotation is inconsistent with the new call.
- If your program (or test suite) passes only `null` as an argument, the inferred type will be the bottom type, such as `@GuardedByBottom`.
- It is common for whole-program inference to infer `@Interned` and `@Regex` annotations on `String` variables for which the analyzed code only uses a constant string.

In each case, you can correct the inferred results manually, or you can add tests that pass additional values then re-run inference.

30.3.3 How whole-program inference works

This section explains how the `infer-and-annotate.sh` script works. If you merely want to run the script and you are not encountering trouble, you can skip this section.

The `infer-and-annotate.sh` script repeatedly runs the following steps:

1. Run the checker with the `-Ainfer` command-line option to infer types for fields and method signatures. The output of this step is a `.jaif` file that records the inferred types.
2. Insert the inferred annotations in the program. This step uses the Annotation File Utilities (<https://checkerframework.org/annotation-file-utilities/>).

The process halts when there are no more changes to the inference results, that is, the `.jaif` file is unchanged between two runs. On each iteration through the process, there may be new annotations in the `.jaif` file, and some type-checking errors may be eliminated (though others might be introduced).

When the type-checker is run on the program with the final annotations inserted, there might still be errors. This may be because the tool did not infer enough annotations, or because your program cannot typecheck (either because contains a defect, or because it contains subtle code that is beyond the capabilities of the type system). However, each of the inferred annotations is sound, and this reduces your manual effort in annotating the program.

The iterative process is required because type-checking is modular: it processes each class and each method only once, independently. Modularity enables you to run type-checking on only part of your program, and it makes type-checking fast. However, it has some disadvantages:

- The first run of the type-checker cannot take advantage of whole-program inference results because whole-program inference is only complete at the end of type-checking, and modular type-checking does not revisit any already-processed classes.
- Revisiting an already-processed class may result in a better estimate.

Chapter 31

Annotating libraries

When your code uses a library that is not currently being compiled, the Checker Framework looks up the library's annotations in its class files. Section 2.2.1 tells you how to find and use a version of a library that contains type annotations.

If your code uses a library that does *not* contain type annotations, then the type-checker has no way to know the library's behavior. The type-checker makes conservative assumptions about unannotated bytecode. (See Section 27.5.6 for details, an example, and how to override this conservative behavior.) These conservative library annotations invariably lead to checker warnings.

This chapter describes how to eliminate the warnings by adding annotations to the library. (Alternately, you can instead suppress all warnings related to an unannotated library, or to part of your codebase, by use of the `-SkipUses` or `-OnlyUses` command-line option; see Sections 28.4–28.5.)

You can write annotations for a library, and make them known to a checker, in two ways.

1. Write annotations in a copy of the library's source code (for instance, in a fork of the library's GitHub project). In addition to writing annotations, adjust the build system to run pluggable-type-checking when compiling (see Chapter 33, page 214). Now, when you compile the library, the resulting `.jar` file contains type annotations. When checking a client of the library, put the annotated library's `.jar` file on the classpath, as explained in Section 2.2.1. With this compilation approach, the syntax of the library annotations is validated ahead of time. Thus, this compilation approach is less error-prone, and the type-checker runs faster. You get correctness guarantees about the library in addition to your code. For instructions, see Section 31.2.
2. Write annotations in a "stub file", if you do not have access to the source code. Then, when check a client of the library, supply the "stub file" textually to the Checker Framework. This approach does not require you to compile the library source code. A stub file is applicable to multiple versions of a library, so the stub file does not need to be updated when a new version of the library is released, unless the API has changed (such as defining a new method). For instructions, see Section 31.5.

If you annotate a new library (either in its source code or in a stub file), please inform the Checker Framework developers so that your annotated library can be distributed with the Checker Framework. Sharing your annotations is useful even if the library is only partially annotated. However, as noted in Sections 2.4.2 and 31.1.4, you should annotate an entire class at a time. You may find type inference tools (Chapter 30.2, page 180) helpful when getting started, but you should always examine their results.

31.1 Tips for annotating a library

Section 2.4 gives general tips for writing annotations. This section gives tips that are specific to annotating a third-party library.

31.1.1 Don't change the code

If you annotate a library that you maintain, you can refactor it to improve its design.

When you annotate a library that you do not maintain, you should only add annotations and, when necessary, documentation of those annotations. You can place the documentation in a Java comment (`//` or `/*...*/`) or in a `@CFComment` annotation.

Do not change the library's code, which will change its behavior and make the annotated version inconsistent with the unannotated version. (Sometimes it is acceptable to make a refactoring, such as extracting an expression into a new local variable in order to annotate its type or suppress a warning. Perform refactoring only when you cannot use `@AssumeAssertion`.)

Do not change publicly-visible documentation, such as Javadoc comments. That also makes the annotated version inconsistent with the unannotated version.

Do not change formatting and whitespace.

All of these changes increase the difference between upstream (the original version) and your annotated version. This makes it harder for others to understand what you have done, and they make it harder to pull changes from upstream into the annotated library.

31.1.2 Library annotations should reflect the specification, not the implementation

Publicly-visible annotations (including those on public method formal parameters and return types) should be based on the documentation, typically the method's Javadoc. In other words, your annotations should re-state facts that are in the Javadoc documentation.

Do not add requirements or guarantees beyond what the library author has already committed to. If a project's Javadoc says nothing about nullness, then you should not assume that the specification forbids null, nor that it permits it. (If the project's Javadoc explicitly mentions null everywhere it is permitted, then you can assume it is forbidden elsewhere, where the author omitted those statements.)

If a fact is not mentioned in the documentation, then it is usually an implementation detail. Clients should not depend on implementation details, which are prone to change without notice. (In some cases, you can infer some facts from the implementation, such as that null is permitted for a method's parameter or return type if the implementation explicitly passes null to the method or the method implementation returns null.)

If there is a fact that you think should be in the library's documentation but was unintentionally omitted by its authors, then please submit a bug report asking them to update the documentation to reflect this fact. After they do, you can also express the fact as an annotation.

31.1.3 Report bugs upstream

While annotating the library, you may discover bugs or missing/wrong documentation. If you have a documentation improvement or a bug fix, then open a pull request against the upstream version of the library. This will benefit all users of the library. And, once the documentation is updated, you will be able to add annotations that are consistent with the documentation.

31.1.4 Fully annotate the library, or indicate which parts you did not

If you do not annotate all the files in the library, then use `@AnnotatedFor` to indicate what files you have annotated.

Whenever you annotate any part of a file, fully annotate the file! That is, write annotations for all the methods and fields, based on their documentation. If you don't annotate the whole file, then users may be surprised that calls to some methods type-check as expected whereas other methods do not (because they have not been annotated).

31.1.5 Verify your annotations

Ideally, after you annotate a file, you should type-check the file to verify the correctness and completeness of your annotations.

An alternative is to only annotate method signatures. The alternative is quicker but more error-prone. There is no difference from the point of view of clients, who can only see annotations on public methods and fields. When you compile the library, the type-checker will probably issue warnings; you can supply `-Awarns` so that the compiler will still produce `.class` files.

31.2 Creating an annotated library

This section describes how to create an annotated library.

1. See the the `org.checkerframework.annotatedlib` group in the Central Repository to find out whether an annotated version of the library already exists.
 - If it exists, but you want to add annotations for a different checker:
Clone its repository from `https://github.com/typetools/`, and tweak its buildfile to run an additional checker.
 - If it does not already exist:
Fork the project. (First, verify that its license permits forking.)
Add a line in its main README to indicate that this is an annotated version of the library. That line should also indicate how to obtain the corresponding upstream version (typically a git tag corresponding to a release), so that others can see exactly what edits you have made.
Adjust the library's build process, such as an Ant, Gradle, or Maven buildfile. Every time the build system runs the compiler, it should:
 - pass the `-AuseConservativeDefaultsForUncheckedCode=source,bytecode` command-line option and
 - run every pluggable type-checker for which any annotations exist, using `-processor TypeSystem1,TypeSystem2`.You are not adding new build targets, but modifying existing targets. The reason to run every type-checker is to verify the annotations you wrote, and to use appropriate defaults for all unannotated type uses.
2. Annotate some files.
When you annotate a file, annotate the whole thing, not just a few of its methods. Add an `@AnnotatedFor({"checkername"})` annotation to each class declaration, or augment an existing `@AnnotatedFor` annotation.
3. Build the library.
Because of the changes that you made in step 1, this will run pluggable type-checkers. If there are any compiler warnings, fix them and re-compile.
Now you have a `.jar` file that you can use while type-checking and at run time.
4. Tell other people about your work so that they can benefit from it.
 - Please inform the Checker Framework developers about your new annotated library by opening a pull request or an issue. This will let us add your annotations to a repository in `https://github.com/typetools/` and upload a compiled artifact to the Maven Central Repository.
 - Optionally, encourage the library's maintainers to accept your annotations into its main version control repository. This suggestion will be most compelling if you have already reported bugs in the library that were revealed by pluggable type-checking. Once the annotations are in the main version control repository, they will be easier to maintain, the library will obtain the correctness guarantees of pluggable type-checking, and there will be no need to distribute an annotated version of the library.
If the library maintainers do not accept the annotations, then periodically, such as when a new version of the library is released, pull changes from upstream (the library's main version control system) into your fork, add annotations to any newly-added methods in classes that are annotated with `@AnnotatedFor`, rebuild to create an updated `.jar` file, and inform the Checker Framework developers by opening an issue or issuing a pull request.

31.3 Creating an annotated JDK

When you create a new checker, you need to also supply annotations for parts of the JDK. You can do so either as stub files or in a copy of the JDK source code. This section describes the latter approach. It assumes that you have already followed the instructions for building the Checker Framework from source (Section 35.3). (Section 35.2.1 tells how to improve JDK annotations for an existing type system.)

Edit files in repository <https://github.com/typetools/jdk>. Add an `@AnnotatedFor()` annotation to each file you annotate.

Whenever you add a file, fully annotate it, as described in Section 31.1.

If you are only annotating fields and method signatures (but not ensuring that method bodies type-check), then you don't need to suppress warnings, because the JDK is not type-checked.

31.4 Compiling partially-annotated libraries

If you *completely* annotate a library, then you can compile it using a pluggable type-checker. You get a guarantee that the library contains no errors (that is, it is consistent with the specifications you wrote).

The rest of this section tells you how to compile a library if you *partially* annotate it: that is, you write annotations for some of its classes but not others. (There is another type of partial annotation, which is when you annotate method signatures but do not type-check the bodies. See Section 31.1.)

Here are two concerns you may have when partially annotating a library:

- Ignoring type-checking errors in unannotated parts of the library. Use the `-AskipDefs` or `-AonlyDefs` command-line arguments; see Section 28.5.
- Putting conservative annotations in unannotated parts of the library. The checker needs to use normal defaulting rules (Section 27.5.3) for code you have annotated and conservative defaulting rules (Section 27.5.6) for code you have not yet annotated. This section describes how to do this. You use `@AnnotatedFor` to indicate which classes you have annotated.

31.4.1 The `-AuseConservativeDefaultsForUncheckedCode=source,bytecode` command-line argument

When compiling a library that is not fully annotated, use command-line argument `-AuseConservativeDefaultsForUncheckedCode=source,bytecode`. This causes the checker to behave normally for classes with a relevant `@AnnotatedFor` annotation. For classes without `@AnnotatedFor`, the checker uses conservative defaults (see Section 27.5.6) for any type use with no explicit user-written annotation, and the checker issues no warnings.

The `@AnnotatedFor` annotation, written on a class, indicates that the class has been annotated for certain type systems. For example, `@AnnotatedFor({"nullness", "regex"})` means that the programmer has written annotations for the Nullness and Regular Expression type systems. If one of those two type-checkers is run, the `-AuseConservativeDefaultsForUncheckedCode=source,bytecode` command-line argument has no effect and this class is treated normally: unannotated types are defaulted using normal source-code defaults and type-checking warnings are issued. `@AnnotatedFor`'s arguments are any string that may be passed to the `-processor` command-line argument: the fully-qualified class name for the checker, or a shorthand for built-in checkers (see Section 2.2.4). Writing `@AnnotatedFor` on a class doesn't necessarily mean that you wrote any annotations, but that the user examined the source code and verified that all appropriate annotations are present.

Whenever you compile a class using the Checker Framework, including when using the `-AuseConservativeDefaultsForUncheckedCode=source,bytecode` command-line argument, the resulting `.class` files are fully-annotated; each type use in the `.class` file has an explicit type qualifier for any checker that is run.

31.5 Using stub classes

A “stub class” is Java source code that is allowed to omit certain parts, such as method bodies. (See Section 31.5.3 for details about the stub file format.) You use a stub file to write annotations for a library, when you cannot edit and recompile the library. A checker uses the annotated signatures at compile time, instead of or in addition to annotations that appear in the library’s `.class` files.

Section 31.3 explains how you should choose between creating stub classes or creating an annotated library. Section 31.5.4 describes how to create stub classes. Section 31.5.1 describes how to use stub classes. These sections illustrate stub classes via the example of creating a `@Interned`-annotated version of `java.lang.String`. You don’t need to repeat these steps to handle `java.lang.String` for the Interning Checker, but you might do something similar for a different class and/or checker.

31.5.1 Using a stub file

The `-Astubs` argument causes the Checker Framework to read annotations from annotated stub classes in preference to the unannotated original library classes. For example:

```
javac -processor org.checkerframework.checker.interning.InterningChecker -Astubs=String.astub:stubs MyFile.java MyOtherFile.java ...
```

Each stub path entry is a stub file (ending with `.astub`), directory, or `.jar` file; specifying a directory or `.jar` file is equivalent to specifying every file in it whose name ends with `.astub`. The stub path entries are delimited by `File.pathSeparator` (`:` for Linux and Mac, `;` for Windows).

A checker automatically reads some of its own stub files, even without a `-Astubs` command-line argument; see Section 32.10.

31.5.2 Multiple specifications for a method

A file being compiled takes precedence over a stub file. If file `A.java` is being compiled, then any stub for class `A` is ignored.

A stub file takes precedence over bytecode, for elements in the stub file. If a stub file does not mention a method or field, its annotations are taken from bytecode. An un-annotated type variable in a stub file is used instead of annotations on a type variable in bytecode. This feature allows stub files to change the effective annotations in all possible situations. Use the `-AstubWarnIfRedundantWithBytecode` command-line option to get a warning whenever a stub file specification is redundant with bytecode annotations.

If a method appears in more than one stub file (or twice in the same stub file), then the annotations are merged. If any of the methods have different annotations from the same hierarchy on the same type, then the annotation from the last declaration is used.

The annotated JDK is read as a stub file.

31.5.3 Stub file format

Every Java file is a valid stub file. However, you can omit information that is not relevant to pluggable type-checking; this makes the stub file smaller and easier for people to read and write. Also note that the stub file’s extension must be `.astub`, not `.java`.

As an illustration, a stub file for the Interning type system (Chapter 6) could be:

```
import org.checkerframework.checker.interning.qual.Interned;
package java.lang;
@Interned class Class<T> {}
class String {
    @Interned String intern();
}
```

The stub file format is allowed to differ from Java source code in the following ways:

Method bodies: The stub class does not require method bodies for classes; any method body may be replaced by a semicolon (;), as in an interface or abstract method declaration.

Method declarations: You only have to specify the methods that you need to annotate. Any method declaration may be omitted, in which case the checker reads its annotations from library's .class files. (If you are using a stub class, then typically the library is unannotated.)

Declaration specifiers: Declaration specifiers (e.g., `public`, `final`, `volatile`) may be omitted.

Return types: The return type of a method does not need to match the real method. In particular, it is valid to use `java.lang.Object` for every method. This simplifies the creation of stub files.

Import statements: Imports may appear at the beginning of the file or after any package declaration. The only required import statements are the ones to import type annotations. Import statements for types are optional.

Multiple classes and packages: The stub file format permits having multiple classes and packages. The packages are separated by a package statement: `package my.package;`. Each package declaration may occur only once; in other words, all classes from a package must appear together.

31.5.4 Creating a stub file

Stub files are generally stored together with the checker implementation, in the same directory as the checker's .java source code.

If you have access to the Java source code

Every Java file is a stub file. If you have access to the Java file, rename file `A.java` to `A.astub`. You can add annotations to the signatures, leaving the method bodies unchanged. The stub file parser silently ignores any annotations that it cannot resolve to a type, so don't forget the `import` statement.

Optionally (but highly recommended!), run the type-checker to verify that your annotations are correct. When you run the type-checker on your annotations, there should not be any stub file that also contains annotations for the class. In particular, if you are type-checking the JDK itself, then you should use the `-Aignorejdkastub` command-line option.

This approach retains the original documentation and source code, making it easier for a programmer to double-check the annotations. It also enables creation of diffs, easing the process of upgrading when a library adds new methods. And, the annotations are in a format that the library maintainers can even incorporate.

The downside of this approach is that the stub files are larger. This can slow down the Checker Framework, because it parses the stub files each time it runs.

Alternatively, you can minimize source files to make them more suitable as stub files. Use the `JavaStubifier` to convert, in-place, all .java files in given directories into minimal stub files.

```
mkdir project-stubs
cp -R project/src project-stubs
java -cp $CHECKERFRAMEWORK/checker/dist/checker.jar org.checkerframework.framework.stub.JavaStubifier pr
find project-stubs -type f -name "*.java" -exec rename 's/.java$/.astub/' {} \;
```

Supply it a list of directories to process. Replacement happens in-place, so make sure to process a copy of your sources.

You can now provide `project-stubs` as a stub directory using `-Astubs=project-stubs` as an additional command-line option.

If you wish to use a single stub file, rather than a stub directory, you can concatenate all the minimized .java files into a single .astub file:

```
find project-stubs/ -name "*.java" -type f | xargs cat > project.astub
```

If you do not have access to the Java source code

If you do not have access to the library source code, then you can create a stub file from the class file (Section 31.5.4), and then annotate it. The rest of this section describes this approach.

1. Create a stub file by running the stub class generator. (`checker.jar` must be on your classpath.)

```
cd nullness-stub
java -cp $CHECKERFRAMEWORK/checker/dist/checker.jar org.checkerframework.framework.stub.StubGenerator
```

Supply it with the fully-qualified name of the class for which you wish to generate a stub class. The stub class generator prints the stub class to standard out, so you may wish to redirect its output to a file.

2. Add import statements for the annotations. So you would need to add the following import statement at the beginning of the file:

```
import org.checkerframework.checker.interning.qual.*;
```

The stub file parser silently ignores any annotations that it cannot resolve to a type, so don't forget the import statement. Use the `-AstubWarnIfNotFound` command-line option to see warnings if an entry could not be found.

3. Add annotations to the stub class. For example, you might annotate the `String.intern()` method as follows:

```
@Interned String intern();
```

You may also remove irrelevant parts of the stub file; see Section 31.5.3.

31.5.5 Troubleshooting stub libraries

Type-checking does not yield the expected results

By default, the stub parser silently ignores annotations on unknown classes and methods. The stub parser also silently ignores unknown annotations, so don't forget to `import` any annotations. Some command-line options make the stub parser issue more warnings:

-AstubWarnIfNotFound Warn whenever some element of a stub file cannot be found. The `@NoStubParserWarning` annotation on a package or type in a stub file overrides the `-AstubWarnIfNotFound` command-line option, and no warning will be issued.

-AstubWarnIfNotFoundIgnoresClasses Modifies the behavior of `-AstubWarnIfNotFound` to report only missing methods/fields, but ignore missing classes, even if other classes from the same package are present. Useful if a package spans more than one jar.

Finally, use command-line option **-AstubDebug** to output debugging messages while parsing stub files, including about unknown classes, methods, and annotations. This overrides the `@NoStubParserWarning` annotation.

Problems parsing stub libraries

When using command-line option `-AstubWarnIfNotFound`, an error is issued if a stub file has a typo or the API method does not exist.

Fix an error of the form

```
StubParser: Method isLLowerCase(char) not found in type java.lang.Character
```

by removing the extra "L" in the method name.

Fix an error of the form

```
StubParser: Method enableForegroundNdefPush(Activity,NdefPushCallback)
not found in type android.nfc.NfcAdapter
```

by removing the method `enableForgroundNdefPush(...)` from the stub file, because it is not defined in class `android.nfc.NfcAdapter` in the version of the library you are using.

31.6 Troubleshooting/debugging annotated libraries

Sometimes, it may seem that a checker is treating a library as unannotated even though the library has annotations. The compiler has two flags that may help you in determining whether library files are read, and if they are read whether the library's annotations are parsed.

- verbose Outputs info about compile phases — when the compiler reads/parses/attributes/writes any file. Also outputs the classpath and sourcepath paths.
- XDTA:parser (which is equivalent to -XDTA:reader plus -XDTA:writer) Sets the internal debugJSR308 flag, which outputs information about reading and writing.

Chapter 32

How to create a new checker

This chapter describes how to create a checker — a type-checking compiler plugin that detects bugs or verifies their absence. After a programmer annotates a program, the checker verifies that the code is consistent with the annotations. If you only want to *use* a checker, you do not need to read this chapter. There is also a developer manual for people who wish to edit the Checker Framework source code or make pull requests.

Writing a simple checker is easy! For example, here is a complete, useful type-checker:

```
import java.lang.annotation.Documented;
import java.lang.annotation.Target;
import java.lang.annotation.ElementType;
import org.checkerframework.common.subtyping.qual.Unqualified;
import org.checkerframework.framework.qual.SubtypeOf;

@Documented
@Target({ElementType.TYPE_USE, ElementType.TYPE_PARAMETER})
@SubtypeOf(Unqualified.class)
public @interface Encrypted {}
```

This checker is so short because it builds on the Subtyping Checker (Chapter 24). See Section 24.2 for more details about this particular checker. When you wish to create a new checker, it is often easiest to begin by building it declaratively on top of the Subtyping Checker, and then return to this chapter when you need more expressiveness or power than the Subtyping Checker affords.

Three choices for creating your own checker are:

- Customize an existing checker. Checkers that are designed for extension include the Subtyping Checker (Chapter 24, page 138), the Fake Enumeration Checker (Chapter 9, page 80), and the Units Checker (Chapter 17, page 114).
- Follow the instructions in this chapter to create a checker from scratch. This enables creation of checkers that are more powerful than customizing an existing checker.
- Copy and then modify a different existing checker — whether one distributed with the Checker Framework or a third-party one. You can get tangled up if you don't fully understand the subtleties of the existing checker that you are modifying. Usually, it is easier to follow the instructions in this chapter. (If you are going to copy a checker, one good choice to copy and modify is the Regex Checker (Chapter 11, page 87). A bad choice is the Nullness Checker (Chapter 3, page 27), which is more sophisticated than anything you want to start out building.)

You do not need all of the details in this chapter, at least at first. In addition to reading this chapter of the manual, you may find it helpful to examine the implementations of the checkers that are distributed with the Checker Framework. The Javadoc documentation of the framework and the checkers is in the distribution and is also available online at <https://checkerframework.org/api/>.

If you write a new checker and wish to advertise it to the world, let us know so we can mention it in Chapter 25, page 143 or even include it in the Checker Framework distribution.

32.1 How checkers build on the Checker Framework

This table shows the relationship among tools that the Checker Framework builds on or that are built on the Checker Framework. You use the Checker Framework to build pluggable type systems, and the Annotation File Utilities to manipulate `.java` and `.class` files.

Subtyping Checker	Nullness Checker	Index Checker	Tainting Checker	...	Your Checker		
Base Checker (enforces subtyping rules)						Type inference	Other tools
Checker Framework (enables creation of pluggable type-checkers)						Annotation File Utilities (<code>.java</code> ↔ <code>.class</code> files)	
Java type annotations syntax and classfile format (no built-in semantics)							

The Base Checker (more precisely, the `BaseTypeChecker`) enforces the standard subtyping rules. The Subtyping Checker is a simple use of the Base Checker that supports providing type qualifiers on the command line. You usually want to build your checker on the Base Checker.

32.2 The parts of a checker

The Checker Framework provides abstract base classes (default implementations), and a specific checker overrides as little or as much of the default implementations as necessary. To simplify checker implementations, by default the Checker Framework automatically discovers the parts of a checker by looking for specific files. Thus, checker implementations follow a very formulaic structure. To illustrate, a checker for `MyProp` must be laid out as follows:

```
myPackage/
| qual/                type qualifiers
| MyPropChecker.java   [optional] interface to the compiler
| MyPropVisitor.java   [optional] type rules
| MyPropAnnotatedTypeFactory.java [optional] type introduction and dataflow rules
```

Note that `MyPropChecker.java` is required unless you are building on the Subtyping Checker.

Sections 32.5–32.9 describe the individual components of a type system as written using the Checker Framework:

32.5 Type qualifiers and hierarchy. You define the annotations for the type system and the subtyping relationships among qualified types (for instance, `@NonNull Object` is a subtype of `@Nullable Object`). This is also where you specify the default annotation that applies whenever the programmer wrote no annotation and no other defaulting rule applies.

32.6 Interface to the compiler. The compiler interface indicates which annotations are part of the type system, which command-line options and `@SuppressWarnings` annotations the checker recognizes, etc.

32.7 Type rules. You specify the type system semantics (type rules), violation of which yields a type error. A type system has two types of rules.

- Subtyping rules related to the type hierarchy, such as that in every assignment, the type of the right-hand-side is a subtype of the type of the left-hand-side. Your checker automatically inherits these subtyping rules from the Base Checker (Chapter 24), so there is nothing for you to do.
- Additional rules that are specific to your particular checker. For example, in the Nullness type system, only references whose type is `@NonNull` may be dereferenced. You write these additional rules yourself.

32.8 Type introduction rules. You specify the type of some expressions where the rules differ from the built in framework rules

32.9 Dataflow rules. These optional rules enhance flow-sensitive type qualifier inference (also known as local variable type inference).

32.3 Compiling and using a custom checker

You can place your checker’s source files wherever you like. One choice is to write your checker in a fork of the Checker Framework repository <https://github.com/typetools/checker-framework>. Another choice is to write it in a stand-alone repository. Here is a template for a stand-alone repository: <https://github.com/typetools/templatefor-a-checker>; at that URL, click the “Use this template” button.

Once your custom checker is written, using it is very similar to using a built-in checker (Section 2.2): simply pass the fully-qualified name of your `BaseTypeChecker` subclass to the `-processor` command-line option:

```
javac -processor mypackage.MyPropChecker SourceFile.java
```

Note that your custom checker’s `.class` files must be on the Java classpath. Invoking a custom checker that builds on the Subtyping Checker is slightly different (Section 24.1).

32.4 Tips for creating a checker

To make your job easier, we recommend that you build your type-checker incrementally, testing at each phase rather than trying to build the whole thing at once.

Here is a good way to proceed.

1. Write the user manual. Do this before you start coding. The manual explains the type system, what it guarantees, how to use it, etc., from the point of view of a user. Writing the manual will help you flesh out your goals and the concepts, which are easier to understand and change in text than in an implementation. Section 32.13 gives a suggested structure for the manual chapter, which will help you avoid omitting any parts. Get feedback from someone else at this point to ensure that your manual is comprehensible.

Once you have designed and documented the parts of your type system, you should “play computer”, manually type-checking some code according to the rules you defined. During manual checking, ask yourself what reasoning you applied, what information you needed, and whether your written-down rules were sufficient. It is more efficient to find problems now rather than after coding up your design.

2. Implement the type qualifiers and hierarchy (Section 32.5).

Write simple test cases that consist of only assignments, to test your type hierarchy. For instance, if your type hierarchy consists of a supertype `@UnknownSign` and a subtype `@NonNegative`, then you could write a test case such as:

```
void testHierarchy(@UnknownSign int us, @NonNegative int nn) {
    @UnknownSign int a = us;
    @UnknownSign int b = nn;
    // :: error: assignment.type.incompatible
    @NonNegative int c = us; // expected error on this line
    @NonNegative int d = nn;
}
```

Type-check your test files using the Subtyping Checker (Chapter 24, page 138).

3. Write the checker class itself (Section 32.6).

Ensure that you can still type-check your test files and that the results are the same. You will not use the Subtyping Checker any more; you will call the checker directly, as in

```
javac -processor mypackage.MyChecker File1.java File2.java ...
```

4. Test infrastructure. If your checker source code is in a clone of the Checker Framework repository, integrate your checker with the Checker Framework's Gradle targets for testing (Section 32.11). This will make it much more convenient to run tests, and to ensure that they are passing, as your work proceeds.

5. Annotate parts of the JDK, if relevant (Section 32.10).

Write test cases for a few of the annotated JDK methods to ensure that the annotations are being properly read by your checker.

6. Implement type rules, if any (Section 32.7). (Some type systems need JDK annotations but don't have any additional type rules.)

Before implementing type rules (or any other code in your type-checker), read the Javadoc to familiarize yourself with the utility routines in the `org.checkerframework.javacutil` package, especially `AnnotationBuilder`, `AnnotationUtils`, `ElementUtils`, `TreeUtils`, `TypeAnnotationUtils`, and `TypesUtils`. You will learn how to access needed information and avoid reimplementing existing functionality.

Write simple test cases to test the type rules, and ensure that the type-checker behaves as expected on those test files. For example, if your type system forbids indexing an array by a possibly-negative value, then you would write a test case such as:

```
void testArrayIndexing(String[] myArray, @UnknownSign int us, @NonNegative int nn) {
    myArray[us]; // expected error on this line
    myArray[nn];
}
```

7. Implement type introduction rules, if any (Section 32.8).

Test your type introduction rules. For example, if your type system sets the qualifier for manifest literal integers and for array lengths, you would write a test case like the following:

```
void testTypeIntroduction(String[] myArray) {
    @NonNegative nn1 = -1; // expected error on this line
    @NonNegative nn2 = 0;
    @NonNegative nn3 = 1;
    @NonNegative nn4 = myArray.length;
}
```

8. Optionally, implement dataflow refinement rules (Section 32.9).

Test them if you wrote any. For instance, if after an arithmetic comparison, your type system infers which expressions are now known to be non-negative, you could write a test case such as:

```
void testDataflow(@UnknownSign int us, @NonNegative int nn) {
    @NonNegative nn2;
    nn2 = us; // expected error on this line
    if (us > j) {
        nn2 = us;
    }
    if (us >= j) {
        nn2 = us;
    }
    if (j < us) {
        nn2 = us;
    }
    if (j <= us) {
        nn2 = us;
    }
    nn = us; // expected error on this line
}
```

32.5 Annotations: Type qualifiers and hierarchy

A type system designer specifies the qualifiers in the type system (Section 32.5.1) and the type hierarchy that relates them. The type hierarchy — the subtyping relationships among the qualifiers — can be defined either declaratively via meta-annotations (Section 32.5.2), or procedurally through subclassing `QualifierHierarchy` or `TypeHierarchy` (Section 32.5.3).

32.5.1 Defining the type qualifiers

Type qualifiers are defined as Java annotations. In Java, an annotation is defined using the Java `@interface` keyword. Here is how to define a two-qualifier hierarchy:

```
package mypackage.qual;
import java.lang.annotation.Documented;
import java.lang.annotation.ElementType;
import java.lang.annotation.Retention;
import java.lang.annotation.RetentionPolicy;
import java.lang.annotation.Target;
import org.checkerframework.framework.qual.DefaultQualifierInHierarchy;
import org.checkerframework.framework.qual.SubtypeOf;
/**
 * The run-time value of the integer is unknown.
 *
 * @checker_framework.manual #nonnegative-checker Non-Negative Checker
 */
@Documented
@Retention(RetentionPolicy.RUNTIME)
@Target({ElementType.TYPE_USE, ElementType.TYPE_PARAMETER})
@SubtypeOf({})
@DefaultQualifierInHierarchy
public @interface UnknownSign {}
```

```
package mypackage.qual;
import java.lang.annotation.Documented;
import java.lang.annotation.ElementType;
import java.lang.annotation.Retention;
import java.lang.annotation.RetentionPolicy;
import java.lang.annotation.Target;
import org.checkerframework.framework.qual.LiteralKind;
import org.checkerframework.framework.qual.SubtypeOf;
/**
 * Indicates that the value is greater than or equal to zero.
 *
 * @checker_framework.manual #nonnegative-checker Non-Negative Checker
 */
@Documented
@Retention(RetentionPolicy.RUNTIME)
@Target({ElementType.TYPE_USE, ElementType.TYPE_PARAMETER})
@SubtypeOf({UnknownSign.class})
public @interface NonNegative {}
```

The `@SubtypeOf` meta-annotation indicates the parent in the type hierarchy.

The `@Target` meta-annotation indicates where the annotation may be written. All type qualifiers that users can write in source code should have the value `ElementType.TYPE_USE` and optionally with the additional value of `ElementType.TYPE_PARAMETER`, but no other `ElementType` values.

The annotations should be placed within a directory called `qual`, and `qual` should be placed in the same directory as your checker's source file. The Checker Framework automatically treats any annotation that is declared in the `qual` package as a type qualifier. (See Section 32.6.1 for more details.) For example, the Nullness Checker's source file is located at `.../nullness/NullnessChecker.java`. The `@NonNull` qualifier is defined in file `.../nullness/qual/NonNull.java`.

Your type system should include a top qualifier and a bottom qualifier (Section 32.5.7). The top qualifier is conventionally named `CheckerNameUnknown`. Most type systems should also include a polymorphic qualifier `@PolyMyTypeSystem` (Section 26.2).

Choose good names for the qualifiers, because users will write these in their source code. The Javadoc of every type qualifier should include a precise English description and an example use of the qualifier.

32.5.2 Declaratively defining the qualifier hierarchy

Declaratively, the type system designer uses two meta-annotations (written on the declaration of qualifier annotations) to specify the qualifier hierarchy.

- `@SubtypeOf` denotes that a qualifier is a subtype of another qualifier or qualifiers, specified as an array of class literals. For example, for any type `T`, `@NonNull T` is a subtype of `@Nullable T`:

```
@Target({ElementType.TYPE_USE, ElementType.TYPE_PARAMETER})
@SubtypeOf({ Nullable.class })
public @interface NonNull {}
```

`@SubtypeOf` accepts multiple annotation classes as an argument, permitting the type hierarchy to be an arbitrary DAG.

All type qualifiers, except for polymorphic qualifiers (see below and also Section 26.2), need to be properly annotated with `SubtypeOf`.

The top qualifier is annotated with `@SubtypeOf({})`. The top qualifier is the qualifier that is a supertype of all other qualifiers. For example, `@Nullable` is the top qualifier of the Nullness type system, hence is defined as:

```
@Target({ElementType.TYPE_USE, ElementType.TYPE_PARAMETER})
@SubtypeOf({})
public @interface Nullable {}
```

If the top qualifier of the hierarchy is the generic unqualified type (this is not recommended!), then its children will use `@SubtypeOf(Unqualified.class)`, but no `@SubtypeOf({})` annotation on the top qualifier `Unqualified` is necessary. For an example, see the `Encrypted` type system of Section 24.2.

- `@PolymorphicQualifier` denotes that a qualifier is a polymorphic qualifier. For example:

```
@Target({ElementType.TYPE_USE, ElementType.TYPE_PARAMETER})
@PolymorphicQualifier
public @interface PolyNull {}
```

For a description of polymorphic qualifiers, see Section 26.2. A polymorphic qualifier needs no `@SubtypeOf` meta-annotation and need not be mentioned in any other `@SubtypeOf` meta-annotation.

The declarative and procedural mechanisms for specifying the hierarchy can be used together. In particular, when using the `@SubtypeOf` meta-annotation, further customizations may be performed procedurally (Section 32.5.3) by overriding the `isSubtype` method in the checker class (Section 32.6). However, the declarative mechanism is sufficient for most type systems.

32.5.3 Procedurally defining the qualifier hierarchy

While the declarative syntax suffices for many cases, more complex type hierarchies can be expressed by overriding, in your subclass of `BaseAnnotatedTypeFactory`, either `createQualifierHierarchy` or `createTypeHierarchy` (typically only one of these needs to be overridden). For more details, see the Javadoc of those methods and of the classes `QualifierHierarchy` and `TypeHierarchy`.

The `QualifierHierarchy` class represents the qualifier hierarchy (not the type hierarchy). A type-system designer may subclass `QualifierHierarchy` to express customized qualifier relationships (e.g., relationships based on annotation arguments).

The `TypeHierarchy` class represents the type hierarchy — that is, relationships between annotated types, rather than merely type qualifiers, e.g., `@NonNull Date` is a subtype of `@Nullable Date`. The default `TypeHierarchy` uses `QualifierHierarchy` to determine all subtyping relationships. The default `TypeHierarchy` handles generic type arguments, array components, type variables, and wildcards in a similar manner to the Java standard subtype relationship but with taking qualifiers into consideration. Some type systems may need to override that behavior. For instance, the Java Language Specification specifies that two generic types are subtypes only if their type arguments are identical: for example, `List<Date>` is not a subtype of `List<Object>`, or of any other generic `List`. (In the technical jargon, the generic arguments are “invariant” or “novariant”.)

32.5.4 Defining the default annotation

A type system applies the default qualifier where the user has not written a qualifier (and no other default qualifier is applicable), as explained in Section 27.5.

The type system designer must specify the default annotation. The designer can specify the default annotation declaratively, using the `@DefaultQualifierInHierarchy` meta-annotation. Note that the default will apply to any source code that the checker reads, including stub libraries, but will not apply to compiled `.class` files that the checker reads.

Alternately, the type system designer may specify a default procedurally, by overriding the `GenericAnnotatedTypeFactory.addCheckedCodeDefaults` method. You may do this even if you have declaratively defined the qualifier hierarchy.

If the default qualifier in the type hierarchy requires a value, there are ways for the type system designer to specify a default value both declaratively and procedurally, as well. To do so declaratively, append the string `default value` where `value` is the actual value you want to be the default, after the declaration of the value in the qualifier file. For instance, `int value() default 0;` would make `value` default to zero. Alternatively, the procedural method described above can be used.

The default qualifier applies to most, but not all, unannotated types, Section 27.5.3 other defaulting rules are automatically added to every checker. Also, Section 27.5 describes other meta-annotations used to specify default annotations.

32.5.5 Relevant Java types

Sometimes, a checker only processes certain Java types. For example, the Format String Checker is relevant only to `CharSequence` and its subtypes such as `String`. The `@RelevantJavaTypes` annotation on the checker class indicates that its qualifiers may only be written on those types and no others. All irrelevant types are defaulted to the top annotation.

32.5.6 Do not re-use type qualifiers

Every annotation should belong to only one type system. No annotation should be used by multiple type systems. This is true even of annotations that are internal to the type system and are not intended to be written by the programmer.

Suppose that you have two type systems that both use the same type qualifier `@Bottom`. In a client program, a use of type `T` may require type qualifier `@Bottom` for one type system but a different qualifier for the other type system. There is no annotation that a programmer can write to make the program type-check under both type systems.

This also applies to type qualifiers that a programmer does not write, because the compiler outputs `.class` files that contain an explicit type qualifier on every type — a defaulted or inferred type qualifier if the programmer didn't write a type qualifier explicitly.

32.5.7 Completeness of the type hierarchy

When you define a type system, its type hierarchy must be a lattice: every set of types has a unique least upper bound and a unique greatest lower bound. This implies that there must be a top type that is a supertype of all other types, and there must be a bottom type that is a subtype of all other types. Furthermore, the top type and bottom type should be defined specifically for the type system. Don't reuse an existing qualifier from the Checker Framework such as `@Unqualified`.

It is possible that a single type-checker checks multiple type hierarchies. An example is the Nullness Checker, which has three separate type hierarchies, one each for nullness, initialization, and map keys. In this case, each type hierarchy would have its own top qualifier and its own bottom qualifier; they don't all have to share a single top qualifier or a single bottom qualifier.

Bottom qualifier Your type hierarchy must have a bottom qualifier — a qualifier that is a (direct or indirect) subtype of every other qualifier.

`null` is the bottom type. Because the only value with type `Void` is `null`, uses of the type `Void` are also bottom. (The only exception is if the type system has special treatment for `null` values, as the Nullness Checker does. In that case, add the meta-annotation `@QualifierForLiterals(LiteralKind.NULL)` to the correct qualifier.) This legal code will not type-check unless `null` has the bottom type:

```
<T> T f() {
    return null;
}
```

Some type systems have a special bottom type that is used *only* for the `null` value, and for dead code and other erroneous situations. In this case, users should only write the bottom qualifier on explicit bounds. In this case, the definition of the bottom qualifier should be meta-annotated with:

```
@Target({ElementType.TYPE_USE, ElementType.PARAMETER})
@TargetLocations({TypeUseLocation.EXPLICIT_LOWER_BOUND, TypeUseLocation.EXPLICIT_UPPER_BOUND})
```

Furthermore, by convention the name of such a qualifier ends with “Bottom”.

The hierarchy shown in Figure 3.3 lacks a bottom qualifier, but the actual implementation does contain a (non-user-visible) bottom qualifier.

Top qualifier Your type hierarchy must have a top qualifier — a qualifier that is a (direct or indirect) supertype of every other qualifier. Here is one reason. The default type for local variables is the top qualifier (that type is then flow-sensitively refined depending on what values are stored in the local variable). If there is no single top qualifier, then there is no unambiguous choice to make for local variables.

32.5.8 Annotations whose argument is a Java expression (dependent type annotations)

Sometimes, an annotation needs to refer to a Java expression. Section 27.8 gives examples of such annotations and also explains what Java expressions can and cannot be referred to.

This section explains how to implement a dependent type annotation.

A “dependent type annotation” must have one attribute, `value`, that is an array of strings. The Checker Framework verifies that the annotation's arguments are valid expressions according to the rules of Section 27.8. If the expression is not valid, an error is issued and the string in the annotation is changed to indicate that the expression is not valid.

The Checker Framework standardizes the expression strings. For example, a field `f` can be referred to as either “`f`” or “`this.f`”. If the programmer writes “`f`”, the Checker Framework treats it as if the programmer had written

“this.f”. An advantage of this canonicalization is that comparisons, such as `isSubtype`, can be implemented as string comparisons.

The Checker Framework viewpoint-adapts type annotations on method, constructor, and field declarations at uses for those methods. For example, given the following class

```
class MyClass {
    Object field = ...;
    @Anno("this.field") Object field2 = ...;
}
```

and assuming the variable `myClass` is of type `MyClass`, then the type of `myClass.field` is viewpoint-adapted to `@Anno("myClass.field")`.

To use this built-in functionality, add a `@JavaExpression` annotation to any annotation element that should be interpreted as a Java expression. The type of the element must be an array of `Strings`. If your checker requires special handling of Java expressions, your checker implementation should override `GenericAnnotatedTypeFactory.createDependentTypesHelper` to return a subclass of `DependentTypesHelper`.

Given a specific expression in the program (of type `Tree` or `Node`), a checker may need to obtain its canonical string representation. This enables the checker to create a dependent type annotation that refers to it, or to compare to the string expression of an existing expression annotation. To obtain the string, first create a `FlowExpressions.Receiver` object by calling `internalReprOf(AnnotationProvider, ExpressionTree)` or `internalReprOf(AnnotationProvider, Node)`. Then, call `toString()` on the `FlowExpressions.Receiver` object.

32.5.9 Repeatable annotations

Some pre- and post-condition annotations that have multiple elements (that is, annotations that take multiple arguments) should be repeatable, so that programmers can specify them more than once. An example is `@EnsuresNonNullIf`; it could not be defined with each of its elements being a list, as (for example) `@KeyFor` is.

Make an annotation *A* repeatable by defining a nested annotation (within *A*'s definition) named `List`, and writing `@Repeatable(A.List.class)` on *A*'s definition.

32.6 The checker class: Compiler interface

A checker's entry point is a subclass of `SourceChecker`, and is usually a direct subclass of either `BaseTypeChecker` or `AggregateChecker`. This entry point, which we call the checker class, serves two roles: an interface to the compiler and a factory for constructing type-system classes.

Because the Checker Framework provides reasonable defaults, oftentimes the checker class has no work to do. Here are the complete definitions of the checker classes for the Interning Checker and the Nullness Checker:

```
package my.package;
import org.checkerframework.common.basetype.BaseTypeChecker;
@SupportedLintOptions({"dotequals"})
public final class InterningChecker extends BaseTypeChecker {}
```

```
package my.package;
import org.checkerframework.common.basetype.BaseTypeChecker;
@SupportedLintOptions({"flow", "cast", "cast:redundant"})
public class NullnessChecker extends BaseTypeChecker {}
```

(The `@SupportedLintOptions` annotation is optional, and many checker classes do not have one.)

The checker class bridges between the Java compiler and the checker. It invokes the type-rule check visitor on every Java source file being compiled. The checker uses `SourceChecker.reportError` and `SourceChecker.reportWarning` to issue errors.

Also, the checker class follows the factory method pattern to construct the concrete classes (e.g., visitor, factory) and annotation hierarchy representation. It is a convention that, for a type system named Foo, the compiler interface (checker), the visitor, and the annotated type factory are named as `FooChecker`, `FooVisitor`, and `FooAnnotatedTypeFactory`. `BaseTypeChecker` uses the convention to reflectively construct the components. Otherwise, the checker writer must specify the component classes for construction.

A checker can customize the default error messages through a `Properties`-loadable text file named `messages.properties` that appears in the same directory as the checker class. The property file keys are the strings passed to report (like `type.incompatible`) and the values are the strings to be printed ("cannot assign ..."). The `messages.properties` file only need to mention the new messages that the checker defines. It is also allowed to override messages defined in superclasses, but this is rarely needed. Section 28.1.3 (page 173) discusses best practices when using a message key in a `@SuppressWarnings` annotation.

32.6.1 Indicating supported annotations

A checker must indicate the annotations that it supports (that make up its type hierarchy).

By default, a checker supports all type annotations located in a subdirectory called `qual` that's located in the same directory as the checker. A type annotation is meta-annotated with either `@Target(ElementType.TYPE_USE)` or `@Target(ElementType.TYPE_USE, ElementType.PARAMETER)`.

To indicate support for annotations that are located outside of the `qual` subdirectory, annotations that have other `ElementType` values, checker writers can override the `createSupportedTypeQualifiers` method (see its Javadoc for details). It is required to define `createSupportedTypeQualifiers` if you are mixing qualifiers from multiple directories (including when extending an existing checker that has its own qualifiers) and when using the Buck build tool, whose classloader cannot find the qualifier directory.

An aggregate checker (which extends `AggregateChecker`) does not need to specify its type qualifiers, but each of its component checkers should do so.

32.6.2 Bundling multiple checkers

Sometimes, multiple checkers work together and should always be run together. There are two different ways to bundle multiple checkers together, by creating either an "aggregate checker" or a "compound checker".

1. An aggregate checker runs multiple independent, unrelated checkers. There is no communication or cooperation among them.

The effect is the same as if a user passes multiple processors to the `-processor` command-line option.

For example, instead of a user having to run

```
javac -processor DistanceUnitChecker,VelocityUnitChecker,MassUnitChecker MyFile.java
```

the user can write

```
javac -processor MyUnitCheckers MyFile.java
```

if you define an aggregate checker class. Extend `AggregateChecker` and override the `getSupportedTypeCheckers` method, like the following:

```
public class MyUnitCheckers extends AggregateChecker {
    protected Collection<Class<? extends SourceChecker>> getSupportedCheckers() {
        return Arrays.asList(DistanceUnitChecker.class,
                             VelocityUnitChecker.class,
                             MassUnitChecker.class);
    }
}
```

An example of an aggregate checker is `I18nChecker` (see Chapter 14.2, page 104), which consists of `I18nSubChecker` and `LocalizableKeyChecker`.

2. Use a compound checker to express dependencies among checkers. Suppose it only makes sense to run `MyChecker` if `MyHelperChecker` has already been run; that might be the case if `MyHelperChecker` computes some information that `MyChecker` needs to use.

Override `MyChecker.getImmediateSubcheckerClasses` to return a list of the checkers that `MyChecker` depends on. Every one of them will be run before `MyChecker` is run. One of `MyChecker`'s subcheckers may itself be a compound checker, and multiple checkers may declare a dependence on the same subchecker. The Checker Framework will run each checker once, and in an order consistent with all the dependences.

A checker obtains information from its subcheckers (those that ran before it) by querying their `AnnotatedTypeFactory` to determine the types of variables. Obtain the `AnnotatedTypeFactory` by calling `getTypeFactoryOfSubchecker`.

32.6.3 Providing command-line options

A checker can provide two kinds of command-line options: boolean flags and named string values (the standard annotation processor options).

Boolean flags

To specify a simple boolean flag, add:

```
@SupportedLintOptions({"myflag"})
```

to your checker subclass. The value of the flag can be queried using

```
checker.getLintOption("myflag", false)
```

The second argument sets the default value that should be returned.

To pass a flag on the command line, call `javac` as follows:

```
javac -processor MyChecker -Alint=myflag
```

Named string values

For more complicated options, one can use the standard `@SupportedOptions` annotation on the checker, as in:

```
@SupportedOptions({"myoption"})
```

The value of the option can be queried using

```
checker.getOption("myoption")
```

To pass an option on the command line, call `javac` as follows:

```
javac -processor MyChecker -Amyoption=p1,p2
```

The value is returned as a single string and you have to perform the required parsing of the option.

32.7 Visitor: Type rules

A type system's rules define which operations on values of a particular type are forbidden. These rules must be defined procedurally, not declaratively. Put them in a file `MyCheckerVisitor.java` that extends `BaseTypeVisitor`.

`BaseTypeVisitor` performs type-checking at each node of a source file's AST. It uses the visitor design pattern to traverse Java syntax trees as provided by Oracle's `jdk.compiler` API, and it issues a warning (by calling `SourceChecker.report`) whenever the type system is violated.

Most type-checkers override only a few methods in `BaseTypeVisitor`. A checker’s visitor overrides one method in the base visitor for each special rule in the type qualifier system. The last line of the overridden version is “`return super.visitTreeType(node, p);`”. If the method didn’t raise any error, the superclass implementation can perform standard checks.

By default, `BaseTypeVisitor` performs subtyping checks that are similar to Java subtype rules, but taking the type qualifiers into account. `BaseTypeVisitor` issues these errors:

- invalid assignment (`type.incompatible`) for an assignment from an expression type to an incompatible type. The assignment may be a simple assignment, or pseudo-assignment like return expressions or argument passing in a method invocation

In particular, in every assignment and pseudo-assignment, the left-hand side of the assignment is a supertype of (or the same type as) the right-hand side. For example, this assignment is not permitted:

```
@Nullable Object myObject;  
@NonNull Object myNonNullObject;  
...  
myNonNullObject = myObject; // invalid assignment
```

- invalid generic argument (`type.argument.type.incompatible`) when a type is bound to an incompatible generic type variable
- invalid method invocation (`method.invocation.invalid`) when a method is invoked on an object whose type is incompatible with the method receiver type
- invalid overriding parameter type (`override.parameter.invalid`) when a parameter in a method declaration is incompatible with that parameter in the overridden method’s declaration
- invalid overriding return type (`override.return.invalid`) when a parameter in a method declaration is incompatible with that parameter in the overridden method’s declaration
- invalid overriding receiver type (`override.receiver.invalid`) when a receiver in a method declaration is incompatible with that receiver in the overridden method’s declaration

32.7.1 AST traversal

The Checker Framework needs to do its own traversal of the AST even though it operates as an ordinary annotation processor [Dar06]. Java provides a visitor for Java code that is intended to be used by annotation processors, but that visitor only visits the public elements of Java code, such as classes, fields, methods, and method arguments — it does not visit code bodies or various other locations. The Checker Framework hardly uses the built-in visitor — as soon as the built-in visitor starts to visit a class, then the Checker Framework’s visitor takes over and visits all of the class’s source code.

Because there is no standard API for the AST of Java code¹, the Checker Framework uses the `javac` implementation. This is why the Checker Framework is not deeply integrated with Eclipse or IntelliJ IDEA, but runs as an external tool (see Section 33.7).

32.7.2 Avoid hardcoding

If a method’s contract is expressible in the type system’s annotation syntax, then you should write annotations, in a stub file or annotated JDK (Chapter 31).

Only if the contract is not expressible should you write a type-checking rule for method invocation, where your rule checks the name of the method being called and then treats the method in a special way.

¹Actually, there is a standard API for Java ASTs — JSR 198 (Extension API for Integrated Development Environments) [Cro06]. If tools were to implement it (which would just require writing wrappers or adapters), then the Checker Framework and similar tools could be portable among different compilers and IDEs.

32.8 Type factory: Type introduction rules

The annotated type of expressions and types are defined via type introduction rules in the type factory. For most expressions and types, these rules are the same regardless of the type system. For example, the type of a method invocation expression is the return type of the invoked method viewpoint-adapted for the call site. The framework implements these rules so that all type systems automatically use them. For other expressions, such as string literals, their (annotated) types depend on the type system, so the framework provides way to specify what qualifiers should apply to these expressions.

Defaulting rules are type introduction rules for computing the annotated type for an unannotated type; these rules are explained in Section 32.5.4. The meta-annotation `@QualifierForLiterals` can be written on an annotation declaration to specify that that annotation should be applied to the type of literals listed in the meta-annotation.

32.8.1 Procedurally specifying type introduction rules

If the meta-annotations are not sufficiently expressive, then you can write your own type introduction rules. To do so, create a subclass of `AnnotatedTypeFactory` and override its two `addComputedTypeAnnotations` methods.

`AnnotatedTypeFactory`, when given a program expression, returns the expression's type. This should include not only the qualifiers that the programmer explicitly wrote in the source code, but also default annotations and type refinement (see Section 27.4 for explanations of these concepts).

To add type introduction rules, you should override `addComputedTypeAnnotations(Tree, AnnotatedTypeMirror)` (or `addComputedTypeAnnotations(Tree, AnnotatedTypeMirror, boolean)` if extending `GenericAnnotatedTypeFactory`) and `addComputedTypeAnnotations(Element, AnnotatedTypeMirror)`. The methods operate on `AnnotatedTypeMirror`, which is the Checker Framework's representation of an annotated type. The methods can make arbitrary changes to the annotations on a type.

32.9 Dataflow: enhancing flow-sensitive type refinement

By default, every checker performs flow-sensitive type refinement, also known as local type inference, as described in Section 27.7.

This section of the manual explains how to enhance the Checker Framework's built-in type refinement. Most commonly, you will inform the Checker Framework about a run-time test that gives information about the type qualifiers in your type system. Section 27.7.4 (page 164) gives examples of type systems with and without run-time tests.

The steps to customizing type refinement are:

1. §32.9.1 Determine which expressions will be refined.
2. §32.9.2 Create required class and configure its use.
3. §32.9.3 Override methods that handle `Nodes` of interest.
4. §32.9.4 Implement the refinement.

The `Regex Checker`'s dataflow customization for the `RegexUtil.asRegex` run-time check is used as a running example.

If needed, you can find more details about the implementation of type refinement, and the control flow graph (CFG) data structure that it uses, in the `Dataflow Manual`.

32.9.1 Determine expressions to refine the types of

A run-time check or run-time operation involves multiple expressions (arguments, results). Determine which expression the customization will refine. This is usually specific to the type system and run-time test. There is no code to write in this step; you are merely determining the design of your type refinement.

For the program operation `op(a, b)`, you can refine the types in either or both of the following ways:

1. Change the result type of the entire expression `op(a,b)`.

As an example (and as the running example of implementing a dataflow refinement), the `RegexUtil.asRegex` method is declared as:

```
@Regex(0) String asRegex(String s, int groups) { ... }
```

This annotation is sound and conservative: it says that an expression such as `RegexUtil.asRegex(myString, myInt)` has type `@Regex(0) String`. However, this annotation is imprecise. When the `group` argument is known at compile time, a better estimate can be given. For example, `RegexUtil.asRegex(myString, 2)` has type `@Regex(2) String`.

2. Change the type of some other expression, such as `a` or `b`.

As an example, consider an equality test in the Nullness type system:

```
@Nullable String s;  
if (s != null) {  
    ...  
} else {  
    ...  
}
```

The type of `s != null` is always `boolean`. However, in the true branch, the type of `s` can be refined to `@NonNull String`.

If you are refining the types of arguments or the result of a method call, then you may be able to implement your flow-sensitive refinement rules by just writing `@EnsuresQualifier` and/or `@EnsuresQualifierIf` annotations. When this is possible, it is the best approach.

Sections 32.9.2–32.9.4 explain how to create a transfer class when the `@EnsuresQualifier` and `@EnsuresQualifierIf` annotations are insufficient.

32.9.2 Create required class

In the same directory as `MyCheckerChecker.java`, create a class named `MyCheckerTransfer` that extends `CFTransfer`.

Leave the class body empty for now. Your class will add functionality by overriding methods of `CFTransfer`, which performs the default Checker Framework type refinement.

As an example, the Regex Checker’s extended `CFTransfer` is `RegexTransfer`.

(If you disregard the instructions above and choose a different name or a different directory for your `MyCheckerTransfer` class, you will also need to override the `createFlowTransferFunction` method in your type factory to return a new instance of the class.)

(As a reminder, use of `@EnsuresQualifier` and `@EnsuresQualifierIf` may obviate the need for a transfer class.)

32.9.3 Override methods that handle Nodes of interest

Decide what source code syntax is relevant to the run-time checks or run-time operations you are trying to support. The CFG (control flow graph) represents source code as `Node`, a node in the abstract syntax tree of the program being checked (see “Program representation” below).

In your extended `CFTransfer` override the visitor method that handles the `Nodes` relevant to your run-time check or run-time operation. Leave the body of the overriding method empty for now.

For example, the Regex Checker refines the type of a run-time test method call. A method call is represented by a `MethodInvocationNode`. Therefore, `RegexTransfer` overrides the `visitMethodInvocation` method:

```
public TransferResult<CFValue, CFStore> visitMethodInvocation(  
    MethodInvocationNode n, TransferInput<CFValue, CFStore> in) { ... }
```

Program representation

The `Node` subclasses can be found in the `org.checkerframework.dataflow.cfg.node` package. Some examples are `EqualToNode`, `LeftShiftNode`, `VariableDeclarationNode`.

A `Node` is basically equivalent to a javac compiler `Tree`.

See Section 32.14 for more information about `Trees`. As an example, the statement `String a = ""`; is represented as this abstract syntax tree:

```
VariableTree:
  name: "a"
  type:
    IdentifierTree
      name: String
  initializer:
    LiteralTree
      value: ""
```

32.9.4 Implement the refinement

Each visitor method in `CFAbstractTransfer` returns a `TransferResult`. A `TransferResult` represents the refined information that is known after an operation. It has two components: the result type for the `Node` being evaluated, and a map from expressions in scope to estimates of their types (a `Store`). Each of these components is relevant to one of the two cases in Section 32.9.1:

1. Changing the `TransferResult`'s result type changes the type that is returned by the `AnnotatedTypeFactory` for the tree corresponding to the `Node` that was visited. (Remember that `BaseTypeVisitor` uses the `AnnotatedTypeFactory` to look up the type of a `Tree`, and then performs checks on types of one or more `Trees`.)
For example, when `RegexTransfer` evaluates a `RegexUtils.asRegex` invocation, it updates the `TransferResult`'s result type. This changes the type of the `RegexUtils.asRegex` invocation when its `Tree` is looked up by the `AnnotatedTypeFactory`. See below for details.
2. Updating the `Store` treats an expression as having a refined type for the remainder of the method or conditional block. For example, when the `Nullness Checker`'s dataflow evaluates `myvar != null`, it updates the `Store` to specify that the variable `myvar` should be treated as having type `@NonNull` for the rest of the then conditional block. Not all kinds of expressions can be refined; currently method return values, local variables, fields, and array values can be stored in the `Store`. Other kinds of expressions, like binary expressions or casts, cannot be stored in the `Store`.

The rest of this section details implementing the visitor method `RegexTransfer.visitMethodInvocation` for the `RegexUtil.asRegex` run-time test. You can find other examples of visitor methods in `LockTransfer` and `FormatterTransfer`.

1. Determine if the visited `Node` is of interest

A visitor method is invoked for all instances of a given `Node` kind in the program. The visitor must inspect the `Node` to determine if it is an instance of the desired run-time test or operation. For example, `visitMethodInvocation` is called when dataflow processes any method invocation, but the `RegexTransfer` should only refine the result of `RegexUtils.asRegex` invocations:

```
@Override
public TransferResult<CFValue, CFStore> visitMethodInvocation(...)
...
MethodAccessNode target = n.getTarget();
ExecutableElement method = target.getMethod();
Node receiver = target.getReceiver();
if (receiver instanceof ClassNameNode) {
```

```
String receiverName = ((ClassNameNode) receiver).getElement().toString();

// Is this a call to static method isRegex(s, groups) in a class named RegexUtil?
if (receiverName.equals("RegexUtil")
    && ElementUtils.matchesElement(method,
        null, "isRegex", String.class, int.class)) {
    ...
}
```

2. Determine the refined type

Sometimes the refined type is dependent on the parts of the operation, such as arguments passed to it.

For example, the refined type of `RegexUtils.asRegex` is dependent on the integer argument to the method call. The `RegexTransfer` uses this argument to build the resulting type `@Regex(i)`, where `i` is the value of the integer argument. For simplicity the below code only uses the value of the integer argument if the argument was an integer literal. It could be extended to use the value of the argument if it was any compile-time constant or was inferred at compile time by another analysis, such as the Constant Value Checker (Chapter 21, page 127).

```
AnnotationMirror regexAnnotation;
Node count = n.getArgument(1);
if (count instanceof IntegerLiteralNode) {
    // argument is a literal integer
    IntegerLiteralNode iln = (IntegerLiteralNode) count;
    Integer groupCount = iln.getValue();
    regexAnnotation = factory.createRegexAnnotation(groupCount);
} else {
    // argument is not a literal integer; fall back to @Regex(), which is the same as @Regex(0)
    regexAnnotation = AnnotationBuilder.fromClass(factory.getElementUtils(), Regex.class);
}
```

3. Return a `TransferResult` with the refined types

Recall that the type of an expression is refined by modifying the `TransferResult` returned by a visitor method. Since the `RegexTransfer` is updating the type of the run-time test itself, it will update the result type and not the `Store`.

A `CFValue` is created to hold the type inferred. `CFValue` is a wrapper class for values being inferred by dataflow:

```
CFValue newResultValue = analysis.createSingleAnnotationValue(regexAnnotation,
    result.getResultValue().getType().getUnderlyingType());
```

Then, `RegexTransfer`'s `visitMethodInvocation` creates and returns a `TransferResult` using `newResultValue` as the result type.

```
return new RegularTransferResult<>(newResultValue, result.getRegularStore());
```

As a result of this code, when the `Regex Checker` encounters a `RegexUtils.asRegex` method call, the checker will refine the return type of the method if it can determine the value of the integer parameter at compile time.

32.9.5 Disabling flow-sensitive inference

In the uncommon case that you wish to disable the Checker Framework's built-in flow inference in your checker (this is different than choosing not to extend it as described in Section 32.9), put the following two lines at the beginning of the constructor for your subtype of `BaseAnnotatedTypeFactory`:

```
// disable flow inference
super(checker, /*useFlow=*/ false);
```

32.10 Annotated JDK and other annotated libraries

You will need to supply annotations for relevant parts of the JDK; otherwise, your type-checker may produce spurious warnings for code that uses the JDK. You have two options:

- Write JDK annotations in a fork of <https://github.com/typetools/jdk>.

- Write JDK annotations as stub files (partial Java source files). Create a file `jdk.astub` in the checker’s main source directory. You can also create `jdkN.astub` files that contain methods or classes that only exist in certain JDK versions. It will be automatically used by the checker, unless the user supplies the command-line option `-Aignorejdkastub`. You can also supply `.astub` files in that directory for other libraries. You should list those other libraries in a `@StubFiles` annotation on the checker’s main class, so that they will also be automatically used.

32.11 Testing framework

The Checker Framework provides a convenient way to write tests for your checker. Each test case is a Java file, with inline indications of what errors and warnings (if any) a checker should emit. An example is

```
class MyNullnessTest {
    void method() {
        Object nullable = null;
        // :: error: (dereference.of.nullable)
        nullable.toString();
    }
}
```

When the Nullness Checker is run on the above code, it should produce exactly one error, whose suppression key is `dereference.of.nullable`, on the line following the “`// ::`” comment.

The testing infrastructure is extensively documented in file `checker-framework/checker/tests/README`.

If your checker’s source code is within a fork of the Checker Framework repository, then you can copy the testing infrastructure used by some existing type system. Here are some of the tasks you will perform:

- Make sure `all-tests` tests the new checker.

32.12 Debugging options

The Checker Framework provides debugging options that can be helpful when implementing a checker. These are provided via the standard `javac -A` switch, which is used to pass options to an annotation processor.

32.12.1 Amount of detail in messages

- `-AprintAllQualifiers`: print all type qualifiers, including qualifiers meta-annotated with `@InvisibleQualifier`, which are usually not shown.
- `-AprintVerboseGenerics`: print more information about type parameters and wildcards when they appear in warning messages. Supplying this also implies `-AprintAllQualifiers`.
- `-Anomsgtext`: use message keys (such as “`type.invalid`”) rather than full message text when reporting errors or warnings. This is used by the Checker Framework’s own tests, so they do not need to be changed if the English message is updated.
- `-AnoPrintErrorStack`: don’t print a stack trace when an internal Checker Framework error occurs. Setting this option is rare. You should only do it if you have discovered a bug in a checker, you have already reported the bug, and you want to continue using the checker on a large codebase without being inundated in stack traces.

32.12.2 Format of output

- `-Adetailedmsgtext`: Output error/warning messages in a stylized format that is easy for tools to parse. This is useful for tools that run the Checker Framework and parse its output, such as IDE plugins. See the source code of `SourceChecker.java` for details about the format.

The `javac-diagnostic-wrapper` tool can transform `javac`'s textual output into other formats, such as JSON in LSP (Language Server Protocol) format.

32.12.3 Stub and JDK libraries

- `-Aignorejdkastub`: ignore the `jdk.astub` and `jdkN.astub` files in the checker directory. Files passed through the `-Astubs` option are still processed. This is useful when experimenting with an alternative stub file.
- `-ApermitMissingJdk`: don't issue an error if no annotated JDK can be found.
- `-AparseAllJdk`: parse all JDK files at startup rather than as needed.
- `-AstubDebug`: Print debugging messages while processing stub files.

32.12.4 Progress tracing

- `-Afilenames`: print the name of each file before type-checking it. This can be useful for determining that a long compilation job is making progress.
This option can also help to keep a Travis CI job alive (since Travis CI terminates any job that does not produce output for 10 minutes). This does not work if you are using Maven, because with forked compilation, the `maven-compiler-plugin` queues up all the output and then prints it at the end. (Also, the `maven-compiler-plugin` is buggy and sometimes doesn't print any output if it cannot parse it.)
- `-Ashowchecks`: print debugging information for each pseudo-assignment check (as performed by `BaseTypeVisitor`; see Section 32.7).
- `-AshowInferenceSteps`: print debugging information about intermediate steps in method type argument inference (as performed by `DefaultTypeArgumentInference`).

32.12.5 Saving the command-line arguments to a file

- `-AoutputArgsToFile`: This saves the final command-line parameters as passed to the compiler in a file. This file can be used as a script (if the file is marked as executable on Unix, or if it includes a `.bat` extension on Windows) to re-execute the same compilation command. Note that this argument cannot be included in a file containing command-line arguments passed to the compiler using the `@argfile` syntax. Example usage:
`-AoutputArgsToFile=$HOME/scriptfile`

32.12.6 Visualizing the dataflow graph

To understand control flow in your program and the resulting type refinement, you can create a graphical representation of the CFG.

Typical use is:

```
javac -processor myProcessor -Aflowdotdir=. MyClass.java
for dotfile in *.dot; do dot -Tpdf -o $dotfile.pdf $dotfile; done
```

where the first command creates file `someDirectory/myClass.dot` that represents the CFG, and the last command draws the CFG in a PDF file. The `dot` program is part of `Graphviz`.

- `-Aflowdotdir=somedir`: Specify directory for `.dot` files visualizing the CFG. Shorthand for `-Acfgviz=org.checkerframework.dataflow.cfg.DOTCFGVisualizer,outdir=somedir`. The directory must already exist.
- `-Averbosecfg`: Enable additional output in the CFG visualization. Equivalent to passing `verbose` to `cfgviz`, e.g. as in `-Acfgviz=MyVisualizer,verbose`
- `-Acfgviz=VizClassName[,opts,...]`: Mechanism to visualize the control flow graph (CFG) of all the methods and code fragments analyzed by the dataflow analysis (Section 32.9). The graph also contains information about flow-sensitively refined types of various expressions at many program points.

The argument is a comma-separated sequence of values or key-value pairs. The first argument is the fully-qualified name of the `org.checkerframework.dataflow.cfg.CFGVisualizer` implementation that should be used. The remaining values or key-value pairs are passed to `CFGVisualizer.init`.

You can also use `CFGVisualizeLauncher` to generate a DOT or String representation of the control flow graph of a given method in a given class.

- With JDK 8:

```
java -Xbootclasspath/p:$CHECKERFRAMEWORK/checker/dist/javac.jar \  
-cp $CHECKERFRAMEWORK/checker/dist/checker.jar \  
org.checkerframework.dataflow.cfg.CFGVisualizeLauncher \  
MyClass.java output/ -class MyClass -method test -pdf
```

- With JDK 11:

```
java -cp $CHECKERFRAMEWORK/checker/dist/checker.jar \  
org.checkerframework.dataflow.cfg.CFGVisualizeLauncher \  
MyClass.java output/ -class MyClass -method test -pdf
```

The above command will generate the corresponding dot and pdf files for the method `test` in the class `MyClass` in the directory `output`. For more information, run `CFGVisualizeLauncher` with no arguments to see the usage.

32.12.7 Miscellaneous debugging options

- `-AresourceStats`: Whether to output resource statistics at JVM shutdown.

32.12.8 Examples

The following example demonstrates how these options are used:

```
$ javac -processor org.checkerframework.checker.interning.InterningChecker \  
docs/examples/InternedExampleWithWarnings.java -Ashowchecks -Anomsgtext -Afilenames  
  
[InterningChecker] InternedExampleWithWarnings.java  
success (line 18): STRING_LITERAL "foo"  
  actual: DECLARED @org.checkerframework.checker.interning.qual.Interned java.lang.String  
  expected: DECLARED @org.checkerframework.checker.interning.qual.Interned java.lang.String  
success (line 19): NEW_CLASS new String("bar")  
  actual: DECLARED java.lang.String  
  expected: DECLARED java.lang.String  
docs/examples/InterningExampleWithWarnings.java:21: (not.interned)  
  if (foo == bar) {  
    ^  
success (line 22): STRING_LITERAL "foo == bar"  
  actual: DECLARED @org.checkerframework.checker.interning.qual.Interned java.lang.String  
  expected: DECLARED java.lang.String  
1 error
```

32.12.9 Using an external debugger

You can use any standard debugger to observe the execution of your checker.

You can also set up remote (or local) debugging using the following command as a template:

```
java -jar "$CHECKERFRAMEWORK/checker/dist/checker.jar" \  
-J-Xdebug -J-Xrunjdp:transport=dt_socket,server=y,suspend=y,address=5005 \  
-processor org.checkerframework.checker.nullness.NullnessChecker \  
src/sandbox/FileToCheck.java
```

32.13 Documenting the checker

This section describes how to write a chapter for this manual that describes a new type-checker. This is a prerequisite to having your type-checker distributed with the Checker Framework, which is the best way for users to find it and for it to be kept up to date with Checker Framework changes. Even if you do not want your checker distributed with the Checker Framework, these guidelines may help you write better documentation.

When writing a chapter about a new type-checker, see the existing chapters for inspiration. (But recognize that the existing chapters aren't perfect: maybe they can be improved too.)

A chapter in the Checker Framework manual should generally have the following sections:

Chapter: Belly Rub Checker The text before the first section in the chapter should state the guarantee that the checker provides and why it is important. It should give an overview of the concepts. It should state how to run the checker.

Section: Belly Rub Annotations This section includes descriptions of the annotations with links to the Javadoc. Separate type annotations from declaration annotations, and put any type annotations that a programmer may not write (they are only used internally by the implementation) last within variety of annotation.

Draw a diagram of the type hierarchy. A textual description of the hierarchy is not sufficient; the diagram really helps readers to understand the system. The diagram will appear in directory `docs/manual/figures/`; see its README file for tips.

The Javadoc for the annotations deserves the same care as the manual chapter. Each annotation's Javadoc comment should use the `@checker_framework.manual` Javadoc taglet to refer to the chapter that describes the checker; see `ManualTaglet`.

Section: What the Belly Rub Checker checks This section gives more details about when an error is issued, with examples. This section may be omitted if the checker does not contain special type-checking rules — that is, if the checker only enforces the usual Java subtyping rules.

Section: Examples Code examples.

Sometimes you can omit some of the above sections. Sometimes there are additional sections, such as tips on suppressing warnings, comparisons to other tools, and run-time support.

You will create a new `belly-rub-checker.tex` file, then `\input` it at a logical place in `manual.tex` (not necessarily as the last checker-related chapter). Also add two references to the checker's chapter: one at the beginning of chapter 1, and identical text in the appropriate part of Section 27.7.4. And add the file to `docs/manual/Makefile`. Keep the lists appear in the same order as the manual chapters, to help us notice if anything is missing.

For a chapter or (sub)*section, use `\sectionAndLabel{Section title}{section-label}`. Section labels should start with the checker name (as in `bellyrub-examples`) and not with "sec:". Figure labels should start with "*fig-checkername*" and not with "fig:". These conventions are for the benefit of the Hevea program that produces the HTML version of the manual. Use `\begin{figure}` for all figures, including those whose content is a table, in order to have a single consistent numbering for all figures.

Don't forget to write Javadoc for any annotations that the checker uses. That is part of the documentation and is the first thing that many users may see. The documentation for any annotation should include an example use of the annotation. Also ensure that the Javadoc links back to the manual, using the `@checker_framework.manual` custom Javadoc tag.

32.14 javac implementation survival guide

Since this section of the manual was written, the useful "The Hitchhiker's Guide to javac" has become available at <http://openjdk.java.net/groups/compiler/doc/hhgtjavac/index.html>. See it first, and then refer to this section. (This section of the manual should be revised, or parts eliminated, in light of that document.)

A checker built using the Checker Framework makes use of a few interfaces from the underlying compiler (Oracle's OpenJDK javac). This section describes those interfaces.

32.14.1 Checker access to compiler information

The compiler uses and exposes three hierarchies to model the Java source code and classfiles.

Types — Java Language Model API

A `TypeMirror` represents a Java type.

There is a `TypeMirror` interface to represent each type kind, e.g., `PrimitiveType` for primitive types, `ExecutableType` for method types, and `NullType` for the type of the null literal.

`TypeMirror` does not represent annotated types though. A checker should use the Checker Framework types API, `AnnotatedTypeMirror`, instead. `AnnotatedTypeMirror` parallels the `TypeMirror` API, but also presents the type annotations associated with the type.

The Checker Framework and the checkers use the types API extensively.

Elements — Java Language Model API

An `Element` represents a potentially-public declaration that can be accessed from elsewhere: classes, interfaces, methods, constructors, and fields. `Element` represents elements found in both source code and bytecode.

There is an `Element` interface to represent each construct, e.g., `TypeElement` for class/interfaces, `ExecutableElement` for methods/constructors, and `VariableElement` for local variables and method parameters.

If you need to operate on the declaration level, always use elements rather than trees (see below). This allows the code to work on both source and bytecode elements.

Example: retrieve declaration annotations, check variable modifiers (e.g., `strictfp`, `synchronized`)

Trees — Compiler Tree API

A `Tree` represents a syntactic unit in the source code, like a method declaration, statement, block, `for` loop, etc. Trees only represent source code to be compiled (or found in `-sourcepath`); no tree is available for classes read from bytecode.

There is a `Tree` interface for each Java source structure, e.g., `ClassTree` for class declaration, `MethodInvocationTree` for a method invocation, and `ForEachTree` for an enhanced-for-loop statement.

You should limit your use of trees. A checker uses Trees mainly to traverse the source code and retrieve the types/elements corresponding to them. Then, the checker performs any needed checks on the types/elements instead.

Using the APIs

The three APIs use some common idioms and conventions; knowing them will help you to create your checker.

Type-checking: Do not use `instanceof` to determine the class of the object, because you cannot necessarily predict the run-time type of the object that implements an interface. Instead, use the `getKind()` method. The method returns `TypeKind`, `ElementKind`, and `Tree.Kind` for the three interfaces, respectively.

Visitors and Scanners: The compiler and the Checker Framework use the visitor pattern extensively. For example, visitors are used to traverse the source tree (`BaseTypeVisitor` extends `TreePathScanner`) and for type checking (`TreeAnnotator` implements `TreeVisitor`).

Utility classes: Some useful methods appear in a utility class. The OpenJDK convention is that the utility class for a `Foo` hierarchy is `Foos` (e.g., `Types`, `Elements`, and `Trees`). The Checker Framework uses a common `Utils` suffix to distinguish the class names (e.g., `TypesUtils`, `TreeUtils`, `ElementUtils`), with one notable exception: `AnnotatedTypes`.

Equality for annotations

`AnnotationMirror` is an interface that is implemented both by `javac` and the Checker Framework. Using `equals` with one object created by the Checker Framework and one by `javac` will always return `false` even if they represent the same

annotation. Therefore, never use any method that compares `AnnotationMirrors` using `equals`. `AnnotationUtils` has various methods that should be used instead. Also, `AnnotationMirrorMap` and `AnnotationMirrorSet` can be used.

32.14.2 How a checker fits in the compiler as an annotation processor

The Checker Framework builds on the Annotation Processing API introduced in Java 6. A type-checking annotation processor is one that extends `AbstractTypeProcessor`; it gets run on each class source file after the compiler confirms that the class is valid Java code.

The most important methods of `AbstractTypeProcessor` are `typeProcess` and `getSupportedSourceVersion`. The former class is where you would insert any sort of method call to walk the AST, and the latter just returns a constant indicating that we are targeting version 8 of the compiler. Implementing these two methods should be enough for a basic plugin; see the Javadoc for the class for other methods that you may find useful later on.

The Checker Framework uses Oracle's Tree API to access a program's AST. The Tree API is specific to the Oracle OpenJDK, so the Checker Framework only works with the OpenJDK `javac`, not with Eclipse's compiler `ecj`. This also limits the tightness of the integration of the Checker Framework into other IDEs such as IntelliJ IDEA. An implementation-neutral API would be preferable. In the future, the Checker Framework can be migrated to use the Java Model AST of JSR 198 (Extension API for Integrated Development Environments) [Cro06], which gives access to the source code of a method. But, at present no tools implement JSR 198. Also see Section 32.7.1.

Learning more about `javac`

Sun's `javac` compiler interfaces can be daunting to a newcomer, and its documentation is a bit sparse. The Checker Framework aims to abstract a lot of these complexities. You do not have to understand the implementation of `javac` to build powerful and useful checkers. Beyond this document, other useful resources include the Java Infrastructure Developer's guide at http://wiki.netbeans.org/Java_DevelopersGuide and the compiler mailing list archives at <http://mail.openjdk.java.net/pipermail/compiler-dev/> (subscribe at <http://mail.openjdk.java.net/mailman/listinfo/compiler-dev>).

32.15 Integrating a checker with the Checker Framework

To integrate a new checker with the Checker Framework release, perform the following:

- Make sure `check-compilermsgs` and `check-purity` run without warnings or errors.

Chapter 33

Integration with external tools

This chapter discusses how to run a checker from the command line, from a build system, or from an IDE. You can skip to the appropriate section:

- Android (Section 33.1)
- Android Gradle Plugin (Section 33.2)
- Ant (Section 33.3)
- Buck (Section 33.4)
- Command line, via Checker Framework javac wrapper (Section 33.5)
- Command line, via JDK javac (Section 33.6)
- Eclipse (Section 33.7)
- Gradle (Section 33.8)
- IntelliJ IDEA (Section 33.9)
- javac Diagnostics Wrapper (Section 33.10)
- Lombok (Section 33.11)
- Maven (Section 33.12)
- NetBeans (Section 33.13)
- tIDE (Section 33.14)

If your build system or IDE is not listed above, you should customize how it runs the javac command on your behalf. See your build system or IDE documentation to learn how to customize it, adapting the instructions for javac in Section 33.6. If you make another tool support running a checker, please inform us via the mailing list or issue tracker so we can add it to this manual.

All examples in this chapter are in the public domain, with no copyright nor licensing restrictions.

33.1 Android

When creating an Android app, you may wish to use `checker-qual-android` whenever this document mentions `checker-qual`. This can lead to smaller dex files (smaller distributed apps).

The `checker-qual-android` artifact is identical to the `checker-qual` artifact, except that in `checker-qual-android` annotations have classfile retention. The default Android Gradle plugin retains types annotated with `runtime-retention` annotations in the main dex, but strips out `class-retention` annotations.

33.2 Android Studio and the Android Gradle Plugin

Android Studio 3.0 and later, and Android Gradle Plugin 3.0.0 and later, support type annotations. (See <https://developer.android.com/studio/write/java8-support> for more details.) This section explains how to configure

your Android project to use the Checker Framework. All the changes should be made to the module's `build.gradle` file — not the project's `build.gradle` file.

Different changes are required for JDK 8 (Section 33.2.1) and for JDK 9+ (Section 33.2.2).

33.2.1 JDK 8

This section shows what changes to make if you are using JDK 8.

1. In your module's `build.gradle` file, set the source and target compatibility to `JavaVersion.VERSION_1_8`:

```
android {
    ...
    compileOptions {
        sourceCompatibility JavaVersion.VERSION_1_8
        targetCompatibility JavaVersion.VERSION_1_8
    }
}
```

2. Add a build variant for running checkers:

```
android {
    ...
    buildTypes {
        ...
        checkTypes {
            javaCompileOptions.annotationProcessorOptions {
                classNames.add("org.checkerframework.checker.nullness.NullnessChecker")
                // You can pass options like so:
                // javaCompileOptions.annotationProcessorOptions.arguments.put("warns", "")
            }
        }
    }
}
```

3. Add a dependency configuration for the annotated JDK:

```
configurations {
    errorproneJavac {
        description = 'required to run the Checker Framework.'
    }
}
```

4. Declare the Checker Framework dependencies:

```
dependencies {
    ... existing dependencies...
    ext.checkerFrameworkVersion = '3.4.0'
    implementation "org.checkerframework:checker-qual-android:${checkerFrameworkVersion}"
    // or if you use no annotations in source code the above line could be
    // compileOnly "org.checkerframework:checker-qual-android:${checkerFrameworkVersion}"
    annotationProcessor "org.checkerframework:checker:${checkerFrameworkVersion}"
    errorproneJavac 'com.google.errorprone:javac:9+181-r4173-1'
}
```

5. Direct all tasks of type `JavaCompile` used by the `checkTypes` build variant to use the Error Prone compiler:

```
gradle.projectsEvaluated {
    tasks.withType(JavaCompile).all { compile ->
        if (compile.name.contains("CheckTypes")) {
            options.fork = true
            options.forkOptions.jvmArgs += ["-Xbootclasspath/p:${configurations.errorproneJavac.asPath}"]
        }
    }
}
```

6. To run the checkers, build using the `checkTypes` variant:

```
gradlew assembleCheckTypes
```

33.2.2 JDK 11

This section shows what changes to make if you are using JDK 11. They should work for JDK 9+, but we have only tested them with JDK 11.

1. In your module's `build.gradle` file, set the source and target compatibility to `JavaVersion.VERSION_1_8`:

```
android {
    ...
    compileOptions {
        sourceCompatibility JavaVersion.VERSION_1_8
        targetCompatibility JavaVersion.VERSION_1_8
    }
}
```

2. Add a build variant for running checkers:

```
android {
    ...
    buildTypes {
        ...
        checkTypes {
            javaCompileOptions.annotationProcessorOptions {
                classNames.add("org.checkerframework.checker.nullness.NullnessChecker")
                // You can pass options like so:
                // javaCompileOptions.annotationProcessorOptions.arguments.put("warns", "")
            }
        }
    }
}
```

3. Declare the Checker Framework dependencies:

```
dependencies {
    ... existing dependencies...
    ext.checkerFrameworkVersion = '3.4.0'
    implementation "org.checkerframework:checker-qual-android:${checkerFrameworkVersion}"
    // or if you use no annotations in source code the above line could be
    // compileOnly "org.checkerframework:checker-qual-android:${checkerFrameworkVersion}"
    annotationProcessor "org.checkerframework:checker:${checkerFrameworkVersion}"
}
```

4. To run the checkers, build using the `checkTypes` variant:

```
gradlew assembleCheckTypes
```

33.3 Ant task

If you use the Ant build tool to compile your software, then you can add an Ant task that runs a checker. We assume that your Ant file already contains a compilation target that uses the `javac` task, and that the `CHECKERFRAMEWORK` environment variable is set.

1. Set the `jsr308javac` property:

```

<property environment="env"/>

<property name="checkerframework" value="\${env.CHECKERFRAMEWORK}" />

<!-- On Mac/Linux, use the javac shell script; on Windows, use javac.bat -->
<condition property="cfJavac" value="javac.bat" else="javac">
  <os family="windows" />
</condition>

<presetdef name="jsr308.javac">
  <javac fork="yes" executable="\${checkerframework}/checker/bin/\${cfJavac}" >
    <compilerarg value="-version"/>
    <compilerarg value="-implicit:class"/>
  </javac>
</presetdef>

```

2. **Duplicate** the compilation target, then **modify** it slightly as indicated in this example:

```

<target name="check-nullness"
  description="Check for null pointer dereferences"
  depends="clean,...">
  <!-- use jsr308.javac instead of javac -->
  <jsr308.javac ... >
    <compilerarg line="-processor org.checkerframework.checker.nullness.NullnessChecker"/>
    <!-- optional, to not check uses of library methods:
      <compilerarg value="-AskipUses=(java\.awt\.|javax\.swing\.)"/>
    -->
    <compilerarg line="-Xmaxerrs 10000"/>
    ...
  </jsr308.javac>
</target>

```

Fill in each ellipsis (...) from the original compilation target.

In the example, the target is named `check-nullness`, but you can name it whatever you like.

33.3.1 Explanation

This section explains each part of the Ant task.

1. Definition of `jsr308.javac`:

The `fork` field of the `javac` task ensures that an external `javac` program is called. Otherwise, Ant will run `javac` via a Java method call, and there is no guarantee that it will get correct version of `javac`.

The `-version` compiler argument is just for debugging; you may omit it.

The `-implicit:class` compiler argument causes annotation processing to be performed on implicitly compiled files. (An implicitly compiled file is one that was not specified on the command line, but for which the source code is newer than the `.class` file.) This is the default, but supplying the argument explicitly suppresses a compiler warning.

2. The `check-nullness` target:

The target assumes the existence of a `clean` target that removes all `.class` files. That is necessary because Ant's `javac` target doesn't re-compile `.java` files for which a `.class` file already exists.

The `-processor ...` compiler argument indicates which checker to run. You can supply additional arguments to the checker as well.

33.4 Buck

Buck is a build system maintained by Facebook.

Buck has support for annotation processors, but that support is undocumented because the Buck maintainers may change the syntax in the future and they don't wish to ever change anything that is documented.

You can learn more about Buck and annotation processors at these URLs: <https://stackoverflow.com/questions/32915721/documentation-for-annotation-processors-buck>, <https://github.com/facebook/buck/issues/85>.

In order to use Checker Framework with Buck on JDK 8, you first need to place the Error Prone JDK 9 compiler in Buck's bootclasspath (further explanation in Section 33.6.1). To do so, follow the instructions on this page:

<https://github.com/uber/okbuck/wiki/Using-Error-Prone-with-Buck-and-OkBuck#using-error-prone-javac-on->

You only need to follow the instructions to use Error Prone javac on that page, not the instructions to enable Error Prone.

Once you have completed those steps, here is an example BUCK build file showing how to enable Checker Framework:

```
prebuilt_jar(  
  name = 'checker-framework',  
  binary_jar = 'checker-3.4.0.jar',  
  visibility = [ 'PUBLIC' ]  
)  
  
prebuilt_jar(  
  name = 'checker-qual',  
  binary_jar = 'checker-qual-3.4.0.jar',  
  visibility = [ 'PUBLIC' ]  
)  
  
java_library (  
  name = 'hello',  
  srcs = glob(['src/main/java/**/*.java']),  
  java_version = '1.8',  
  provided_deps = [ ':checker-framework', ':checker-qual' ],  
  # To add annotation processing  
  annotation_processors = [ 'org.checkerframework.checker.units.UnitsChecker' ],  
  annotation_processor_deps = [ ':checker-framework', ':checker-qual' ],  
)
```

33.5 Command line, via Checker Framework javac wrapper

To perform pluggable type-checking from the command line, run the `javac` command that ships with the Checker Framework. This is called the “Checker Framework compiler”. It is exactly the same as the OpenJDK `javac` compiler, with one small difference: it includes the Checker Framework jar file on its classpath.

There are three ways to use the Checker Framework compiler from the command line. You can use any one of them. However, if you are using the Windows command shell, you must use the last one.

- **Option 1:** Add directory `../checker-framework-3.4.0/checker/bin` to your path, *before* any other directory that contains a `javac` executable.

If you are using the bash shell, a way to do this is to add the following to your `~/.profile` (or alternately `~/.bash_profile` or `~/.bashrc`) file:

```
export CHECKERFRAMEWORK=${HOME}/checker-framework-3.4.0  
export PATH=${CHECKERFRAMEWORK}/checker/bin:${PATH}
```

then log out and back in to ensure that the environment variable setting takes effect.

- **Option 2:** Whenever this document tells you to run `javac`, instead run ``${CHECKERFRAMEWORK}/checker/bin/javac`.

You can simplify this by introducing an alias `javacheck`. Then, whenever this document tells you to run `javac`, instead run `javacheck`. Here is the syntax for your `~/.bashrc` file:

```
export CHECKERFRAMEWORK=${HOME}/checker-framework-3.4.0
alias javacheck=' $CHECKERFRAMEWORK/checker/bin/javac'
```

- **Option 3: Whenever this document tells you to run `javac`, instead run `checker.jar` via `java` (not `javac`) as in:**

```
java -jar "$CHECKERFRAMEWORK/checker/dist/checker.jar" -cp "myclasspath" -processor nullness MyFile
```

You can simplify the above command by introducing an alias `javacheck`. Then, whenever this document tells you to run `javac`, instead run `javacheck`. For example:

```
# Unix
export CHECKERFRAMEWORK=${HOME}/checker-framework-3.4.0
alias javacheck=' java -jar "$CHECKERFRAMEWORK/checker/dist/checker.jar"'

# Windows
set CHECKERFRAMEWORK = C:\Program Files\checker-framework-3.4.0\
doskey javacheck=java -jar "%CHECKERFRAMEWORK%\checker\dist\checker.jar" %*
```

(Explanation for advanced users: More generally, anywhere that you would use `javac.jar`, you can substitute `$CHECKERFRAMEWORK/checker/dist/checker.jar`; the result is to use the Checker Framework compiler instead of the regular `javac`.)

33.6 Command line, via JDK `javac`

This section explains how to use the Checker Framework with the OpenJDK or OracleJDK `javac`, rather than with the `javac` wrapper script described in Section 33.5.

This section assumes you have downloaded the Checker Framework release zip and set the environment variable `CHECKERFRAMEWORK` to point to the unzipped directory. Alternately, you can get all of the jars mentioned in this section from Maven Central:

- `javac.jar`: <https://search.maven.org/artifact/com.google.errorprone/javac/9%2B181-r4173-1/jar>
- `checker-qual.jar`: <https://search.maven.org/artifact/org.checkerframework/checker-qual/3.4.0/jar>
- `checker.jar`: <https://search.maven.org/artifact/org.checkerframework/checker/3.4.0/jar>

Different arguments to `javac` are required for JDK 8 (Section 33.6.1) and for JDK 9+ (Section 33.6.2).

33.6.1 JDK 8

This section shows what arguments to pass to `javac` to run the Checker Framework, if you are using JDK 8.

```
javac \
-J-Xbootclasspath/p:$CHECKERFRAMEWORK/checker/dist/javac.jar \
-cp $CHECKERFRAMEWORK/checker/dist/checker-qual.jar \
-processorpath $CHECKERFRAMEWORK/checker/dist/checker.jar \
-processor org.checkerframework.checker.nullness.NullnessChecker \
-source 8 -target 8
```

Below is an explanation of each argument.

1. `-J-Xbootclasspath/p:$CHECKERFRAMEWORK/checker/dist/javac.jar`: even when running under JDK 8, a Java 9+ compiler (either the Error Prone compiler or the OpenJDK Java compiler (version 9 or later) must be on the JVM bootclasspath. The `-J` indicates that this is a JVM argument rather than a compiler argument. The following exception is thrown if this argument is missing:

```
error: SourceChecker.typeProcessingStart: unexpected Throwable (NoSuchMethodError);
message: com.sun.tools.javac.code.Type.stripMetadata()Lcom/sun/tools/javac/code/Type;
```

If you are compiling your own checker, the following exception is thrown if this argument is missing:

```
java.lang.NoSuchFieldError: ANNOTATION_PROCESSOR_MODULE_PATH
```

2. `-cp $CHECKERFRAMEWORK/checker/dist/checker-qual.jar`: `checker-qual.jar` must be on the compilation classpath.
3. `-processorpath $CHECKERFRAMEWORK/checker/dist/checker.jar`: `checker.jar` must be on the processor path. Using this option means that the processor path, not the classpath, will be searched for annotation processors.
4. `-processor org.checkerframework.checker.nullness.NullnessChecker`: Choose which checker to run by passing its fully qualified name as a processor. (Note, using this option means that `javac` will not search for annotation processors, but rather will run only those specified here.)
5. `-source 8 -target 8`: Because the build is using a Java 9 compiler, these options ensure that the source code is Java 8 and that Java 8 bytecode is created.

33.6.2 JDK 11

This section shows what arguments to pass to `javac` to run the Checker Framework using JDK 11. These instructions should work on JDK 9 or later, but we only test with JDK 11.

For compiling non-modularized code:

```
javac \  
-J--add-opens=jdk.compiler/com.sun.tools.javac.comp=ALL-UNNAMED \  
-processorpath $CHECKERFRAMEWORK/checker/dist/checker.jar \  
-cp $CHECKERFRAMEWORK/checker/dist/checker-qual.jar \  
-processor org.checkerframework.checker.nullness.NullnessChecker
```

The arguments are explained above, except for `-J--add-opens=jdk.compiler/com.sun.tools.javac.comp=ALL-UNNAMED` which opens the `jdk.compiler/com.sun.tools.java.comp` package. This is required because the Checker Framework reflectively accesses private members of this package.

If this option is missing, `javac` may issue the following warning:

```
WARNING: An illegal reflective access operation has occurred  
WARNING: Illegal reflective access by org.checkerframework.javacutil.Resolver  
  (file:$CHECKERFRAMEWORK/checker/dist/checker.jar) to method com.sun.tools.javac.comp.Resolve.findMethod(  
WARNING: Please consider reporting this to the maintainers of org.checkerframework.javacutil.Resolver  
WARNING: Use --illegal-access=warn to enable warnings of further illegal reflective access operations  
WARNING: All illegal access operations will be denied in a future release
```

For compiling a module, first add `requires org.checkerframework.checker.qual` to your `module-info.java`. The Checker Framework inserts inferred annotations into bytecode even if none appear in source code, so you must do this even if you write no annotations in your code.

```
javac \  
-J--add-opens=jdk.compiler/com.sun.tools.javac.comp=ALL-UNNAMED \  
-processorpath $CHECKERFRAMEWORK/checker/dist/checker.jar \  
--module-path $CHECKERFRAMEWORK/checker/dist/checker-qual.jar \  
-processor org.checkerframework.checker.nullness.NullnessChecker
```

`checker-qual.jar` must be on the module path rather than the class path, but do not put `checker.jar` on the processor module path as it is not modularized.

33.7 Eclipse

You need to run the Checker Framework via a build tool (Ant, Gradle, Maven, etc.), rather than by supplying the `-processor` command-line option to the `ejc` compiler, which is also known as `eclipsec`. The reason is that the Checker Framework is built upon `javac`, and `ejc` represents the Java program differently. (If both `javac` and `ejc` implemented JSR 198 [Cro06], then it would be possible to build an annotation processor that works with both compilers.)

There is no dedicated Eclipse plug-in for running the Checker Framework, but it's still easy to run the Checker Framework. First, create a target/task in your build system to run the Checker Framework. Then, run the target/task from Eclipse. Section 33.7.1 gives details for Ant, but other build systems are similar.

33.7.1 Using an Ant task

Add an Ant target as described in Section 33.3. You can run the Ant target by executing the following steps (instructions copied from http://help.eclipse.org/luna/index.jsp?topic=%2Forg.eclipse.platform.doc.user%2FgettingStarted%2Fqs-84_run_ant.htm):

1. Select `build.xml` in one of the navigation views and choose **Run As > Ant Build...** from its context menu.
2. A launch configuration dialog is opened on a launch configuration for this Ant buildfile.
3. In the **Targets** tab, select the new ant task (e.g., `check-interning`).
4. Click **Run**.
5. The Ant buildfile is run, and the output is sent to the Console view.

33.7.2 Troubleshooting Eclipse

Eclipse issues an “Unhandled Token in `@SuppressWarnings`” warning if you write a `@SuppressWarnings` annotation containing a string that Eclipse does not know about. Unfortunately, Eclipse hard-codes this list.

To eliminate the warnings: disable all “Unhandled Token in `@SuppressWarnings`” warnings in Eclipse. Look under the menu headings “Java → Compiler → Errors/Warnings → Annotations → Unhandled Token in ‘`@SuppressWarnings`’,” and set it to ignore.

33.8 Gradle

To run a checker on a project that uses the Gradle build system, use the Checker Framework Gradle plugin (<https://github.com/kellogg/checkerframework-gradle-plugin>). Its documentation explains how to use it.

33.9 IntelliJ IDEA

This section tells you how to make IntelliJ IDEA automatically run a checker on every compile for Java projects and/or modules.

If your project uses a build tool (Ant, Gradle, Maven, etc.), *do not* use the instructions in this section. Follow the instructions for that build tool instead (they are in a different section of this chapter). To compile your project, run the build tool (possibly from within IntelliJ IDEA, possibly not).

If your project does not use a build tool, use the following instructions to run a checker within IntelliJ IDEA on every compile:

1. Change the project SDK to 11, as explained at <https://www.jetbrains.com/help/idea/sdk.html#change-project-sdk>.
2. Make sure the language level for your project is 8 or higher, as explained at <https://www.jetbrains.com/help/idea/project-page.html>.
3. Create and configure an annotation profile, following the instructions at <https://www.jetbrains.com/help/idea/annotation-processors-support.html>. When configuring the profile:

- (a) Add `.../checker-framework/checker/dist/checker.jar` to the processor path.
 - (b) Add checkers to be run during compilation by writing the fully-qualified name of the checker in the “Processor FQ Name” section.
4. Add `.../checker-framework/checker/dist/checker-qual.jar`, as a dependency to all modules you wish to type check. (They should all have been associated with the annotation profile above.) Instructions appear at <https://www.jetbrains.com/help/idea/creating-and-managing-projects.html>.

Now, when you compile your code, the checker will be run.

It is necessary to manually inform the IDE via a plugin if an annotation system adds any dependencies beyond those that normally exist in Java. For information about the extension points, see <https://youtrack.jetbrains.com/issue/IDEA-159286>.

33.10 javac diagnostics wrapper

The javac diagnostics wrapper project can post-process the javac diagnostics output into other formats, such as the LSP (Language Server Protocol) JSON style.

33.11 Lombok

Project Lombok (<https://projectlombok.org/>) is a library that generates getter, setter, and builder methods, among other features. For example, if you declare a field:

```
@Getter @Setter
private @Regex String role;
```

then Lombok will generate getter and setter methods:

```
public @Regex String getRole() { return role; }
public void setRole(@Regex String role) { this.role = role; }
```

33.11.1 Annotations on generated code

As illustrated in the example above, Lombok copies type annotations from fields to generated methods, when the user writes Lombok’s `@Getter`, `@Setter`, and `@Builder` annotations. Lombok does so only for certain type annotations (including all annotations in the Checker Framework distribution); see variable `BASE_COPYABLE_ANNOTATIONS` in file `HandlerUtil.java`.

To make Lombok copy other type annotations from fields to generated code, add those type annotations to the `lombok.copyableAnnotations` configuration key in your `lombok.config` file. For example:

```
lombok.copyableAnnotations += my.checker.qual.MyTypeAnnotation
```

Directory `docs/examples/lombok` contains an example Gradle project that augments the configuration key.

33.11.2 Type-checking code with Lombok annotations

If you run the Checker Framework and Lombok in the same `javac` invocation, the Checker Framework cannot type-check a class that contains Lombok annotations. The way that Lombok changes the class prevents the Checker Framework from seeing any of the class. (The Checker Framework works fine on classes that do not contain Lombok annotations, including if they call Lombok-generated code.)

Therefore, you must run the Checker Framework in a postpass after the `javac` that runs Lombok has completed. Use the `Delombok` tool (distributed with Lombok) to generate Java source code, then run the Checker Framework on that. The Checker Framework Gradle plugin does this for you automatically.

33.12 Maven

If you use the Maven tool, then you can enable Checker Framework checkers by following the instructions below.

See the directory `docs/examples/MavenExample/` for examples of the use of Maven build files that run a checker with JDK 8. See the directory `docs/examples/MavenExampleJDK11/` for examples of the use of Maven build files that run a checker with JDK 11. These examples can be used to verify that Maven is correctly downloading the Checker Framework from the Maven Central Repository and executing it.

Please note that the `-AoutputArgsToFile` command-line option (see Section 32.12.5) and shorthands for built-in checkers (see Section 2.2.4) are not available when following these instructions. Both these features are available only when a checker is launched via `checker.jar` such as when `$CHECKERFRAMEWORK/checker/bin/javac` is run. The instructions in this section bypass `checker.jar` and cause the compiler to run a checker as an annotation processor directly.

1. Declare a dependency on the Checker Framework artifacts, either from Maven Central or from a local directory. Find the existing `<dependencies>` section and add the following new `<dependency>` items:

- (a) To obtain artifacts from Maven Central:

```
<dependencies>
... existing <dependency> items ...

<!-- Annotations from the Checker Framework: nullness, interning, locking, ... -->
<dependency>
  <groupId>org.checkerframework</groupId>
  <artifactId>checker-qual</artifactId>
  <version>3.4.0</version>
</dependency>
<!-- If using JDK 8, add the following additional dependency. -->
<dependency>
  <groupId>com.google.errorprone</groupId>
  <artifactId>javac</artifactId>
  <version>9+181-r4173-1</version>
</dependency>
</dependencies>
```

Periodically update to the most recent version, to obtain the latest bug fixes and new features:

```
mvn versions:use-latest-versions -Dincludes="org.checkerframework:*"
```

The need for the `com.google.errorprone:javac` artifact when running under JDK 8 is explained in Section 33.6.1.

2. If using JDK 8, use a Maven property to hold the location of the Error Prone `javac.jar`. They were declared as Maven dependencies above. To set the value of these properties automatically, you will use the Maven Dependency plugin.

First, create the property in the properties section of the POM:

```
<properties>
  <!-- These properties will be set by the Maven Dependency plugin -->
  <errorProneJavac>${com.google.errorprone:javac:jar}</errorProneJavac>
</properties>
```

Change the reference to the `maven-dependency-plugin` within the `<plugins>` section, or add it if it is not present.

```
<plugin>
  <!-- This plugin will set properties values using dependency information -->
  <groupId>org.apache.maven.plugins</groupId>
  <artifactId>maven-dependency-plugin</artifactId>
  <executions>
```

```

    <execution>
      <goals>
        <goal>properties</goal>
      </goals>
    </execution>
  </executions>
</plugin>

```

3. Direct the Maven compiler plugin to use the desired checkers. Change the reference to the `maven-compiler-plugin` within the `<plugins>` section, or add it if it is not present.

For example, to use the `org.checkerframework.checker.nullness.NullnessChecker`:

```

<plugin>
  <artifactId>maven-compiler-plugin</artifactId>
  <version>3.8.1</version>
  <configuration>
    <fork>true</fork> <!-- Must fork or else JVM arguments are ignored. -->
    <!-- If using JDK 8, add source and target. -->
    <source>1.8</source>
    <target>1.8</target>
    <!-- If using JDK 11, remove source and target and uncomment "release" below. -->
    <!-- <release>11</release> -->
    <compilerArguments>
      <Xmaxerrs>10000</Xmaxerrs>
      <Xmaxwarns>10000</Xmaxwarns>
    </compilerArguments>
    <!-- Without showWarnings and verbose, maven-compiler-plugin may not show output. -->
    <showWarnings>true</showWarnings>
    <verbose>true</verbose>
    <annotationProcessorPaths>
      <path>
        <groupId>org.checkerframework</groupId>
        <artifactId>checker</artifactId>
        <version>3.4.0</version>
      </path>
    </annotationProcessorPaths>
    <annotationProcessors>
      <!-- Add all the checkers you want to enable here -->
      <annotationProcessor>org.checkerframework.checker.nullness.NullnessChecker</annotationProcessor>
    </annotationProcessors>
    <compilerArgs>
      <!-- If using JDK 8, use only the two arguments immediately below. -->
      <arg>-J-Xbootclasspath/p:${errorProneJavac}</arg>
      <!-- If using JDK 11, remove the two arguments above, remove the
           space in the one below, and uncomment it. -->
      <!-- <arg>-J- -add-opens=jdk.compiler/com.sun.tools.javac.comp=ALL-UNNAMED</arg> -->

      <!-- Optionally, -Awarns turns type-checking errors into warnings. -->
      <!-- <arg>-Awarns</arg> -->
    </compilerArgs>
  </configuration>
</plugin>

```

Now, building with Maven will run the checkers during compilation.

If you want to allow Maven to compile your code without running the checkers, you may want to move the declarations above to within a Maven profile, so that the checkers run only if the profile was enabled.

Warning: adding

```

<compilerArgs>
  ...
  <arg>-verbose</arg>

```

may suppress warnings from the stub parser.

33.12.1 Maven, with a locally-modified version of the Checker Framework

To use a locally-modified version of the Checker Framework, first run:

```
./gradlew deployArtifactsToLocalRepo
```

Then use the Maven instructions, but modify the version number for the Checker Framework artifacts. Instead of 3.4.0, use the version number that is output when you run `./gradlew version`.

33.13 NetBeans

There are two approaches to running a checker in NetBeans: via modifying the project properties, or via a custom ant target.

Note: The “compile and save” action in NetBeans 8.1 automatically runs the Checker Framework, but this functionality has not yet been incorporated into NetBeans 8.2. Additionally, JDK annotations are currently unavailable on NetBeans 8.1 and 8.2.

33.13.1 Adding a checker via the Project Properties window

1. Add the Checker Framework libraries to your project’s library. First, right click on the project in the Projects panel, and select “Properties” in the drop-down menu. Then, in the “Project Properties” window, navigate to the “Libraries” tab.
2. Add `checker-qual.jar` to the compile-time libraries. To do so, select the “Compile” tab, click the “Add JAR/Folder” button on the right and browse to add `$(CHECKERFRAMEWORK)/checker/dist/checker-qual.jar`.
3. Add `checker.jar` to the processor-path libraries. To do so, select the “Processor” tab, click the “Add JAR/Folder” button on the right and browse to add `$(CHECKERFRAMEWORK)/checker/dist/checker.jar`.
4. Enable annotation processor underlining in the editor. Go to “Build>Compiling” and check the box “Enable Annotation Processing,” and under that, “Enable Annotation Processing in Editor.”
5. Add the checker to run, by clicking “Add” next to the box labeled “Annotation Processors” and enter the fully qualified name of the checker (for example, `org.checkerframework.checker.nullness.NullnessChecker`) and click “OK” to add.

The selected checker should be run on the project either on a save (if Compile on Save is enabled), or when the project is built, and annotation processor output will appear in the editor.

33.13.2 Adding a checker via an ant target

1. Set the `jsr308javac` property:

```
<property environment="env"/>

<property name="checkerframework" value="${env.CHECKERFRAMEWORK}" />

<!-- On Mac/Linux, use the javac shell script; on Windows, use javac.bat -->
<condition property="cfJavac" value="javac.bat" else="javac">
  <os family="windows" />
</condition>

<presetdef name="jsr308.javac">
  <javac fork="yes" executable="${checkerframework}/checker/bin/${cfJavac}" >
    <compilerarg value="-version"/>
    <compilerarg value="-implicit:class"/>
  </javac>
</presetdef>
```

2. Override the `-init-macrodef-javac-with-processors` target to use `jsr308.javac` instead of `javac` and to run the checker. In this example, a nullness checker is run:

```

<target depends="-init-ap-commandline-properties" if="ap.supported.internal"
  name="-init-macrodef-javac-with-processors">
  <echo message = "${checkerframework}"/>
  <macrodef name="javac" uri="http://www.netbeans.org/ns/j2se-project/3">
    <attribute default="${src.dir}" name="srcdir"/>
    <attribute default="${build.classes.dir}" name="destdir"/>
    <attribute default="${javac.classpath}" name="classpath"/>
    <attribute default="${javac.processorpath}" name="processorpath"/>
    <attribute default="${build.generated.sources.dir}/ap-source-output" name="apgeneratedsrcdir"/>
    <attribute default="${includes}" name="includes"/>
    <attribute default="${excludes}" name="excludes"/>
    <attribute default="${javac.debug}" name="debug"/>
    <attribute default="${empty.dir}" name="sourcepath"/>
    <attribute default="${empty.dir}" name="gensrcdir"/>
    <element name="customize" optional="true"/>
    <sequential>
      <property location="${build.dir}/empty" name="empty.dir"/>
      <mkdir dir="${empty.dir}"/>
      <mkdir dir="@{apgeneratedsrcdir}"/>
      <jsr308.javac debug="@{debug}" deprecation="${javac.deprecation}"
        destdir="@{destdir}" encoding="${source.encoding}"
        excludes="@{excludes}" fork="${javac.fork}"
        includeantruntime="false" includes="@{includes}"
        source="${javac.source}" sourcepath="@{sourcepath}"
        srcdir="@{srcdir}" target="${javac.target}"
        tmpdir="${java.io.tmpdir}">
      <src>
        <dirset dir="@{gensrcdir}" erroronmissingdir="false">
          <include name="*" />
        </dirset>
      </src>
      <classpath>
        <path path="@{classpath}"/>
      </classpath>
      <compilerarg line="${endorsed.classpath.cmd.line.arg}"/>
      <compilerarg line="${javac.profile.cmd.line.arg}"/>
      <compilerarg line="${javac.compilerargs}"/>
      <compilerarg value="-processorpath"/>
      <compilerarg path="@{processorpath}:${empty.dir}"/>
      <compilerarg line="${ap.processors.internal}"/>
      <compilerarg line="${annotation.processing.processor.options}"/>
      <compilerarg value="-s"/>
      <compilerarg path="@{apgeneratedsrcdir}"/>
      <compilerarg line="${ap.proc.none.internal}"/>
      <compilerarg line="-processor org.checkerframework.checker.nullness.NullnessChecker"/>
      <compilerarg line="-Xmaxerrs 10000"/>
      <compilerarg line="-Xmaxwarns 10000"/>
      <customize/>
    </jsr308.javac>
  </sequential>
</macrodef>
</target>
<target name="-post-jar">
</target>

```

When Build and Clean Project is used, the output of the checker will now appear in the build console. However, annotation processor output will not appear in the editor.

33.14 tIDE

tIDE, an open-source Java IDE, supports the Checker Framework. You can download it from <https://sourceforge.net/projects/tide/>.

33.15 Type inference tools

There are two different tasks that are commonly called “type inference”. You are probably interested in type inference to annotate a program’s source code; see Section 30.2. This section explains the two different varieties of type inference.

33.15.1 Local variable type inference within a method body

While type-checking a method, the type-checker determines types for local variables with no type annotation, and determines more precise types for all expressions (Section 27.7). The type-checker uses those inferred types, but never tells the programmer (or other tools) what it inferred. Each time the type-checker runs, it re-does local type inference.

Local variable type inference is built into the Checker Framework. Every checker can take advantage of it at no extra effort. However, it only works within a method, not across method boundaries. Every method signature (arguments and return values) and field must have already been explicitly annotated, either by the programmer or by a separate type-checking tool (Section 30.2). A programmer rarely writes any qualifiers inside the body of a method (except sometimes on type arguments).

Advantages of this variety of type inference include:

- If the type qualifier is obvious to the programmer, then omitting it can reduce annotation clutter in the program.
- If the code changes, then there is no old annotation to update.
- Inference chooses the most general possible type, which may permit more uses than a programmer-chosen type would have.

33.15.2 Type inference to annotate a program’s source code

As a separate step before type-checking, a type inference tool takes the whole program as input, and outputs a set of type qualifiers that can be inserted into the source code or the class file (Section 30.2). They can be used by other tools.

A programmer runs inference just once. The programmer can view and adjust the annotations before committing them to the source code repository.

This variety of type inference must be provided by a separate tool, before type-checking runs. The Checker Framework comes with such a tool (Section 30.3).

There exist monolithic whole-program analyses that run without requiring any annotations in the source code. Using such an analysis is somewhat similar to running a whole-program inference tool, then running a type-checker. Advantages of the latter two-step approach include:

- The type qualifiers act as machine-checked documentation, which can aid programmer understanding.
- Error messages may be more comprehensible. With a monolithic whole-program analysis, error messages can be obscure, because the analysis has already inferred (possibly incorrect) types for a number of variables.
- Type-checking is modular, which can be faster than re-doing a whole-program analysis every time the program is type-checked.

Chapter 34

Frequently Asked Questions (FAQs)

These are some common questions about the Checker Framework and about pluggable type-checking in general. Feel free to suggest improvements to the answers, or other questions to include here.

Contents:

34.1: Motivation for pluggable type-checking

- 34.1.1: I don't make type errors, so would pluggable type-checking help me?
- 34.1.2: Should I use pluggable types (type qualifiers), or should I use Java subtypes?

34.2: Getting started

- 34.2.1: How do I get started annotating an existing program?
- 34.2.2: Which checker should I start with?
- 34.2.3: How can I join the checker-framework-dev mailing list?

34.3: Usability of pluggable type-checking

- 34.3.1: Are type annotations easy to read and write?
- 34.3.2: Will my code become cluttered with type annotations?
- 34.3.3: Will using the Checker Framework slow down my program? Will it slow down the compiler?
- 34.3.4: How do I shorten the command line when invoking a checker?
- 34.3.5: Method pre-condition contracts, including formal parameter annotations, make no sense for public methods.

34.4: How to handle warnings

- 34.4.1: What should I do if a checker issues a warning about my code?
- 34.4.2: What does a certain Checker Framework warning message mean?
- 34.4.3: What do square brackets mean in a Checker Framework warning message?
- 34.4.4: Can a pluggable type-checker guarantee that my code is correct?
- 34.4.5: What guarantee does the Checker Framework give for concurrent code?
- 34.4.6: How do I make compilation succeed even if a checker issues errors?
- 34.4.7: Why does the checker always say there are 100 errors or warnings?
- 34.4.8: Why does the Checker Framework report an error regarding a type I have not written in my program?
- 34.4.9: Why does the Checker Framework accept code on one line but reject it on the next?
- 34.4.10: How can I do run-time monitoring of properties that were not statically checked?

34.5: False positive warnings

- 34.5.1: What is a "false positive" warning?
- 34.5.2: How can I improve the Checker Framework to eliminate a false positive warning?

- 34.5.3: Why doesn't the Checker Framework infer types for fields and method return types?
- 34.5.4: Why doesn't the Checker Framework track relationships between variables?
- 34.5.5: Why isn't the Checker Framework path-sensitive?

34.6: Syntax of type annotations

- 34.6.1: What is a "receiver"?
- 34.6.2: What is the meaning of an annotation after a type, such as `@NonNull Object @Nullable?`
- 34.6.3: What is the meaning of array annotations such as `@NonNull Object @Nullable []?`
- 34.6.4: What is the meaning of varargs annotations such as `@English String @NonEmpty ...?`
- 34.6.5: What is the meaning of a type qualifier at a class declaration?
- 34.6.6: How are type qualifiers written on upper and lower bounds?
- 34.6.7: Why shouldn't a qualifier apply to both types and declarations?
- 34.6.8: How do I annotate a fully-qualified type name?
- 34.6.9: What is the difference between type annotations and declaration annotations?

34.7: Semantics of type annotations

- 34.7.1: How can I handle typestate, or phases of my program with different data properties?
- 34.7.2: Why are explicit and implicit bounds defaulted differently?
- 34.7.3: Why are type annotations declared with `@Retention(RetentionPolicy.RUNTIME)?`

34.8: Creating a new checker

- 34.8.1: How do I create a new checker?
- 34.8.2: What properties can and cannot be handled by type-checking?
- 34.8.3: Why is there no declarative syntax for writing type rules?

34.9: Tool questions

- 34.9.1: How does pluggable type-checking work?
- 34.9.2: What classpath is needed to use an annotated library?
- 34.9.3: Why do `.class` files contain more annotations than the source code?
- 34.9.4: Is there a type-checker for managing checked and unchecked exceptions?
- 34.9.5: The Checker Framework runs too slowly

34.10: Relationship to other tools

- 34.10.1: Why not just use a bug detector (like FindBugs or Error Prone)?
- 34.10.2: How does the Checker Framework compare with Eclipse's Null Analysis?
- 34.10.3: How does the Checker Framework compare with NullAway?
- 34.10.4: How does the Checker Framework compare with the JDK's `Optional` type?
- 34.10.5: How does pluggable type-checking compare with JML?
- 34.10.6: Is the Checker Framework an official part of Java?
- 34.10.7: What is the relationship between the Checker Framework and JSR 305?
- 34.10.8: What is the relationship between the Checker Framework and JSR 308?

34.1 Motivation for pluggable type-checking

34.1.1 I don't make type errors, so would pluggable type-checking help me?

Occasionally, a developer says that he makes no errors that type-checking could catch, or that any such errors are unimportant because they have low impact and are easy to fix. When I investigate the claim, I invariably find that the developer is mistaken.

Very frequently, the developer has underestimated what type-checking can discover. Not every type error leads to an exception being thrown; and even if an exception is thrown, it may not seem related to classical types. Remember that a type system can discover null pointer dereferences, incorrect side effects, security errors such as information leakage or SQL injection, partially-initialized data, wrong units of measurement, and many other errors. Every programmer makes errors sometimes and works with other people who do. Even where type-checking does not discover a problem directly, it can indicate code with bad smells, thus revealing problems, improving documentation, and making future maintenance easier.

There are other ways to discover errors, including extensive testing and debugging. You should continue to use these. But type-checking is a good complement to these. Type-checking is more effective for some problems, and less effective for other problems. It can reduce (but not eliminate) the time and effort that you spend on other approaches. There are many important errors that type-checking and other automated approaches cannot find; pluggable type-checking gives you more time to focus on those.

34.1.2 Should I use pluggable types (type qualifiers), or should I use Java subtypes?

In brief, use subtypes when you can, and use type qualifiers when you cannot use subtypes.

For some programming tasks, you can use either a Java subtype (interfaces or subclasses) or a type qualifier. As an example, suppose that your code currently uses `String` to represent an address. You could use Java subclasses by creating a new `Address` class and refactor your code to use it, or you could use type qualifiers by creating an `@Address` annotation and applying it to some uses of `String` in your code. As another example, suppose that your code currently uses `MyClass` in two different ways that should not interact with one another. You could use Java subclasses by changing `MyClass` into an interface or abstract class, defining two subclasses, and ensuring that neither subclass ever refers to the other subclass nor to the parent class.

If Java subclasses solve your problem, then that is probably better. We do not encourage you to use type qualifiers as a poor substitute for classes. An advantage of using classes is that the Java type-checker runs every time you compile your code; by contrast, it is possible to forget to run the pluggable type-checker. However, sometimes type qualifiers are a better choice; here are some reasons:

Backward compatibility Using a new class may make your code incompatible with existing libraries or clients. Brian Goetz expands on this issue in an article on the pseudo-typedef antipattern [Goe06]. Even if compatibility is not a concern, a code change may introduce bugs, whereas adding annotations does not change the run-time behavior. It is possible to add annotations to existing code, including code you do not maintain or cannot change. For code that strictly cannot be changed, you can write library annotations (see Chapter 31).

Broader applicability Type annotations can be applied to primitives and to final classes such as `String`, which cannot be subclassed.

Richer semantics and new supertypes Type qualifiers permit you to remove operations, with a compile-time guarantee. More generally, type qualifiers permit creating a new supertype, not just a subtype, of an existing Java type.

More precise type-checking The Checker Framework is able to verify the correctness of code that the Java type-checker would reject. Here are a few examples.

- It uses a dataflow analysis to determine a more precise type for variables after conditional tests or assignments.
- It treats certain Java constructs more precisely, such as reflection (see Chapter 23).
- It includes special-case logic for type-checking specific methods, such as the Nullness Checker's treatment of `Map.get`.

Efficiency Type qualifiers have no run-time representation. Therefore, there is no space overhead for separate classes or for wrapper classes for primitives. There is no run-time overhead for due to extra dereferences or dynamic dispatch for methods that could otherwise be statically dispatched.

Less code clutter The programmer does not have to convert primitive types to wrappers, which would make the code both uglier and slower. Thanks to defaults and type inference (Section 27.5), you may be able to write and think in terms of the original Java type, rather than having to explicitly write one of the subtypes in all locations.

For more details, see Section 34.1.2.

34.2 Getting started

34.2.1 How do I get started annotating an existing program?

See Section 2.4.2.

34.2.2 Which checker should I start with?

You should start with a property that matters to you. Think about what aspects of your code cause the most errors, or cost the most time during maintenance, or are the most common to be incorrectly-documented. Focusing on what you care about will give you the best benefits.

When you first start out with the Checker Framework, it's usually best to get experience with an existing type-checker before you write your own new checker.

Many users are tempted to start with the Nullness Checker (see Chapter 3, page 27), since null pointer errors are common and familiar. The Nullness Checker works very well, but be warned of three facts that make the absence of null pointer exceptions challenging to verify.

1. Dereferences happen throughout your codebase, so there are a lot of potential problems. By contrast, fewer lines of code are related to locking, regular expressions, etc., so those properties are easier to check.
2. Programmers use `null` for many different purposes. More seriously, programmers write run-time tests against `null`, and those are difficult for any static analysis to capture.
3. The Nullness Checker interacts with initialization and map keys.

If null pointer exceptions are most important to you, then by all means use the Nullness Checker. But if you just want to try *some* type-checker, there are others that are easier to use.

We do not recommend indiscriminately running all the checkers on your code. The reason is that each one has a cost — not just at compile time, but also in terms of code clutter and human time to maintain the annotations. If the property is important to you, is difficult for people to reason about, or has caused problems in the past, then you should run that checker. For other properties, the benefits may not repay the effort to use it. You will be the best judge of this for your own code, of course.

Some of the third-party checkers (see Chapter 25, page 143) have known bugs that limit their usability. (Report the ones that affect you, so the developers will prioritize fixing them.)

34.2.3 How can I join the checker-framework-dev mailing list?

The `checker-framework-dev@googlegroups.com` mailing list is for Checker Framework developers. Anyone is welcome to join `checker-framework-dev`, after they have had several pull requests accepted.

Anyone is welcome to send mail to the `checker-framework-dev@googlegroups.com` mailing list — for implementation details it is generally a better place for discussions than the general `checker-framework-discuss@googlegroups.com` mailing list, which is for user-focused discussions.

Anyone is welcome to join `checker-framework-discuss@googlegroups.com` and send mail to it.

34.3 Usability of pluggable type-checking

34.3.1 Are type annotations easy to read and write?

The papers “Practical pluggable types for Java” [PAC⁺08] and “Building and using pluggable type-checkers” [DDE⁺11] discuss case studies in which programmers found type annotations to be natural to read and write. The code continued to feel like Java, and the type-checking errors were easy to comprehend and often led to real bugs.

You don't have to take our word for it, though. You can try the Checker Framework for yourself.

The difficulty of adding and verifying annotations depends on your program. If your program is well-designed and -documented, then skimming the existing documentation and writing type annotations is extremely easy. Otherwise, you may find yourself spending a lot of time trying to understand, reverse-engineer, or fix bugs in your program, and then just a moment writing a type annotation that describes what you discovered. This process inevitably improves your code. You must decide whether it is a good use of your time. For code that is not causing trouble now and is unlikely to do so in the future (the code is bug-free, and you do not anticipate changing it or using it in new contexts), then the effort of writing type annotations for it may not be justified.

34.3.2 Will my code become cluttered with type annotations?

In summary: annotations do not clutter code; they are used much less frequently than generic types, which Java programmers find acceptable; and they reduce the overall volume of documentation that a codebase needs.

As with any language feature, it is possible to write ugly code that over-uses annotations. However, in normal use, very few annotations need to be written. Figure 1 of the paper Practical pluggable types for Java [PAC⁺08] reports data for over 350,000 lines of type-annotated code:

- 1 annotation per 62 lines for nullness annotations (`@NonNull`, `@Nullable`, etc.)
- 1 annotation per 1736 lines for interning annotations (`@Interned`)

These numbers are for annotating existing code. New code that is written with the type annotation system in mind is cleaner and more correct, so it requires even fewer annotations.

Each annotation that a programmer writes replaces a sentence or phrase of English descriptive text that would otherwise have been written in the Javadoc. So, use of annotations actually reduces the overall size of the documentation, at the same time as making it machine-processable and less ambiguous.

34.3.3 Will using the Checker Framework slow down my program? Will it slow down the compiler?

Using the Checker Framework has no impact on the execution of your program: the compiler emits the identical bytecodes as the Java 8 compiler and so there is no run-time effect. Because there is no run-time representation of type qualifiers, there is no way to use reflection to query the qualifier on a given object, though you can use reflection to examine a class/method/field declaration.

Using the Checker Framework does increase compilation time. In theory it should only add a few percent overhead, but our current implementation can double the compilation time — or more, if you run many pluggable type-checkers at once. This is especially true if you run pluggable type-checking on every file (as we recommend) instead of just on the ones that have recently changed. Nonetheless, compilation with pluggable type-checking still feels like compilation, and you can do it as part of your normal development process.

34.3.4 How do I shorten the command line when invoking a checker?

The compile options to `javac` can be long to type; for example, `javac -processor org.checkerframework.checker.nullness.NullnessChecker ...`. See Section 2.2.3 for a way to avoid the need for the `-processor` command-line option.

34.3.5 Method pre-condition contracts, including formal parameter annotations, make no sense for public methods

Some people go further and say that pre-condition contracts make no sense for any method. This objection is sometimes stated as, "A method parameter should never be annotated as `@NonNull`. A client could pass any value at all, so the method implementation cannot depend on the value being non-null. Furthermore, if a client passes an illegal value, it is the method's responsibility to immediately tell the client about the illegal value."

Here is an example that invalidates this general argument. Consider a binary search routine. Its specification requires that clients pass in a sorted array.

```
/** Return index of the search key, if it is contained in the sorted array a; otherwise ... */
int binarySearch(Object @Sorted [] a, Object key)
```

The `binarySearch` routine is fast — it runs in $O(\log n)$ time where n is the length of the array. If the routine had to validate that its input array is sorted, then it would run in $O(n)$ time, negating all benefit of binary search. In other words, `binarySearch` should *not* validate its input!

The nature of a contract is that if the *caller* violates its responsibilities by passing bad values, then the *callee* is absolved of its responsibilities. It is polite for the callee to try to provide a useful diagnostic to the misbehaving caller (for example, by raising a particular exception quickly), but it is *not* required. In such a situation, the callee has the flexibility to do anything that is convenient.

In some cases a routine has a *complete* specification: the contract permits the caller to pass any value, and the callee is required to throw particular exceptions for particular inputs. This approach is common for public methods, but it is not required and is not always the right thing. As explained in section 2.4.3, even when a method has a complete specification, the annotations should indicate normal behavior: behavior that will avoid exceptions.

34.4 How to handle warnings and errors

34.4.1 What should I do if a checker issues a warning about my code?

For a discussion of this issue, see Section 2.4.5.

34.4.2 What does a certain Checker Framework warning message mean?

Read the error message first; sometimes that is enough to clarify it.

Search through this manual for the text of the warning message or for words that appear in it.

If nothing else explains it, then ask on the mailing list. Be sure to say what you think it means or what specific part does not make sense to you, and what you have already done to try to understand it.

34.4.3 What do square brackets mean in a Checker Framework warning message?

In a message like this:

```
found   : ? extends T extends @UnknownKeyFor Object
required: [extends @UnknownKeyFor Object super @UnknownKeyFor null]
```

the square brackets enclose the upper and lower bounds that the type parameter needs to be within.

34.4.4 Can a pluggable type-checker guarantee that my code is correct?

Each checker looks for certain errors. You can use multiple checkers to detect more errors in your code, but you will never have a guarantee that your code is completely bug-free.

If the type-checker issues no warning, then you have a guarantee that your code is free of some particular error. There are some limitations to the guarantee.

Most importantly, if you run a pluggable checker on only part of a program, then you only get a guarantee that those parts of the program are error-free. For example, suppose you have type-checked a framework that clients are intended to extend. You should recommend that clients run the pluggable checker. There is no way to force users to do so, so you may want to retain dynamic checks or use other mechanisms to detect errors.

Section 2.3 states other limitations to a checker's guarantee, such as regarding concurrency. Java's type system is also unsound in certain situations, such as for arrays and casts (however, the Checker Framework is sound for arrays and casts). Java uses dynamic checks in some places it is unsound, so that errors are thrown at run time. The pluggable

type-checkers do not currently have built-in dynamic checkers to check for the places they are unsound. Writing dynamic checkers would be an interesting and valuable project.

Other types of dynamism in a Java application do not jeopardize the guarantee, because the type-checker is conservative. For example, at a method call, dynamic dispatch chooses some implementation of the method, but it is impossible to know at compile time which one it will be. The type-checker gives a guarantee no matter what implementation of the method is invoked.

Even if a pluggable checker cannot give an ironclad guarantee of correctness, it is still useful. It can find errors, exclude certain types of possible problems (e.g., restricting the possible class of problems), improve documentation, and increase confidence in your software.

34.4.5 What guarantee does the Checker Framework give for concurrent code?

The Lock Checker (see Chapter 7) offers a way to detect and prevent certain concurrency errors.

By default, the Checker Framework assumes that the code that it is checking is sequential: that is, there are no concurrent accesses from another thread. This means that the Checker Framework is unsound for concurrent code, in the sense that it may fail to issue a warning about errors that occur only when the code is running in a concurrent setting. For example, the Nullness Checker issues no warning for this code:

```
if (myobject.myfield != null) {
    myobject.myfield.toString();
}
```

This code is safe when run on its own. However, in the presence of multithreading, the call to `toString` may fail because another thread may set `myobject.myfield` to `null` after the nullness check in the `if` condition, but before the `if` body is executed.

If you supply the `-AconcurrentSemantics` command-line option, then the Checker Framework assumes that any field can be changed at any time. This limits the amount of type refinement (Section 27.7) that the Checker Framework can do.

34.4.6 How do I make compilation succeed even if a checker issues errors?

Section 2.2 describes the `-Awarns` command-line option that turns checker errors into warnings, so type-checking errors will not cause `javac` to exit with a failure status.

34.4.7 Why does the checker always say there are 100 errors or warnings?

By default, `javac` only reports the first 100 errors or warnings. Furthermore, once `javac` encounters an error, it doesn't try compiling any more files (but does complete compilation of all the ones that it has started so far).

To see more than 100 errors or warnings, use the `javac` options `-Xmaxerrs` and `-Xmaxwarns`. To convert Checker Framework errors into warnings so that `javac` will process all your source files, use the option `-Awarns`. See Section 2.2 for more details.

34.4.8 Why does the Checker Framework report an error regarding a type I have not written in my program?

Sometimes, a Checker Framework warning message will mention a type you have not written in your program. This is typically because a default has been applied where you did not write a type; see Section 27.5. In other cases, this is because type refinement has given an expression a more specific type than you wrote or than was defaulted; see Section 27.7. Note that an invocation of an impure method may cause the loss of all information that was determined via type refinement; see Section 27.7.5.

34.4.9 Why does the Checker Framework accept code on one line but reject it on the next?

Sometimes, the Checker Framework permits code on one line, but rejects the same code a few lines later:

```
if (myField != null) {
    myField.hashCode();    // no warning
    someMethod();
    myField.hashCode();    // warning about potential NullPointerException
}
```

The reason is explained in the section on type refinement (Section 27.7), which also tells how to specify the side effects of `someMethod` (Section 27.7.5).

34.4.10 How can I do run-time monitoring of properties that were not statically checked?

Some properties are not checked statically (see Chapter 28 for reasons that code might not be statically checked). In such cases, it would be desirable to check the property dynamically, at run time. Currently, the Checker Framework has no support for adding code to perform run-time checking.

Adding such support would be an interesting and valuable project. An example would be an option that causes the Checker Framework to automatically insert a run-time check anywhere that static checking is suppressed. If you are able to add run-time verification functionality, we would gladly welcome it as a contribution to the Checker Framework.

Some checkers have library methods that you can explicitly insert in your source code. Examples include the Nullness Checker's `NullnessUtil.castNonNull` method (see Section 3.4.1) and the Regex Checker's `RegexUtil` class (see Section 11.2.4). But, it would be better to have more general support that does not require the user to explicitly insert method calls.

34.5 False positive warnings

34.5.1 What is a “false positive” warning?

A “false positive” is when the tool reports a potential problem, but the code is actually correct and will never violate the given property at run time.

The Checker Framework aims to be sound; that is, if the Checker Framework does not report any possible errors, then your code is correct.

Every sound tool suffers false positive errors. Wherever the Checker Framework issues an error, you can think of it as saying, “I can't prove this code is safe,” but the code might be safe for some complex, tricky reason that is beyond the capabilities of its analysis.

If you are sure that the warning is a false positive, you have several options. Perhaps you just need to write annotations, especially on method signatures but perhaps within method bodies as well. Sometimes you can rewrite the code in a clearer way that the Checker Framework can verify, and that might be easier for people to understand, too. If these don't work, then you can suppress the warning (Section 2.4.5). You also might want to report the false positive in the Checker Framework issue tracker (Section 35.2), if it appears in real-world, well-written code. Finally, you could improve the Checker Framework to make it more precise, so that it does not suffer that false positive (see Section 34.5.2).

34.5.2 How can I improve the Checker Framework to eliminate a false positive warning?

As noted in Section 34.5.1, *every* sound analysis tool suffers false positives.

For any given false positive warning, it is theoretically possible to improve the Checker Framework to eliminate it. (But, it's theoretically impossible to eliminate all false positives. That is, there will always exist some programs that don't go wrong at run time but for which the Checker Framework issues a warning.)

Some improvements affect the implementation of the type system; they do not add any new types. Such an improvement is invisible to users, except that the users suffer fewer false positive warnings. This type of improvement to the type checker's implementation is often worthwhile.

Other improvements change the type system or add a new type system. Defining new types is a powerful way to improve precision, but it is costly too. A simpler type system is easier for users to understand, less likely to contain bugs, and more efficient.

By design, each type system in the Checker Framework has limited expressiveness. Our goal is to implement enough functionality to handle common, well-written real-world code, not to cover every possible situation.

When reporting bugs, please focus on realistic scenarios. We are sure that you can make up artificial code that stymies the type-checker! Those bugs aren't a good use of your time to report nor the maintainers' time to evaluate and fix. When reporting a bug, it's very helpful to minimize it to give a tiny example that is easy to evaluate and fix, but please also indicate how it arises in real-world, well-written code.

34.5.3 Why doesn't the Checker Framework infer types for fields and method return types?

Consider the following code. A programmer can tell that all three invocations of `format` are safe — they never suffer an `IllegalFormatException` exception at run time:

```
class MyClass {  
  
    final String field = "%d";  
  
    String method() {  
        return "%d";  
    }  
  
    void method m() {  
        String local = "%d";  
        String.format(local, 5);    // Format String Checker verifies the call is safe  
        String.format(field, 5);    // Format String Checker warns the call might not be safe  
        String.format(method(), 5); // Format String Checker warns the call might not be safe  
    }  
}
```

However, the Format String Checker can only verify the first call. It issues a false positive warning about the second and third calls.

The Checker Framework can verify all three calls, with no false positive warnings, if you annotate the type of `field` and the return type of `method` as `@Format(INT)`.

By default, the Checker Framework infers types for local variables (Section 27.7), but not for fields and method return types. (The Checker Framework includes a whole-program type inference tool that infers field and method return types; see Section 30.3.) There are several reasons for this design choice.

Separation of specification from implementation The designer of an API makes certain promises to clients; these are codified in the API's specification or contract. The implementation might return a more specific type today, but the designer does not want clients to depend on that. For example, a string might happen to be a regular expression because it contains no characters with special meaning in regexes, but that is not guaranteed to always be true. It's better for the programmer to explicitly write the intended specification.

Separate compilation To infer types for a non-final method, it is necessary to examine every overriding implementation, so that the method's return type annotation is compatible with all values that are returned by any overriding implementation. In general, examining all implementations is impossible, because clients may override the method. When possible, it is inconvenient to provide all that source code, and it would slow down the type-checker.

A related issue is that determining which values can be returned by a method m requires analyzing m 's body, which requires analyzing all the methods called by m , and so forth. This quickly devolves to analyzing the whole program. Determining all possible values assigned to a field is equally hard.

Type-checking is modular — it works on one procedure at a time, examining that procedure and the specifications (not implementations) of methods that it calls. Therefore, type-checking is fast and can work on partial programs. The Checker Framework performs modular type-checking, not a whole-program analysis.

Order of compilation When the compiler is called on class `Client` and class `Library`, the programmer has no control over which class is analyzed first. When the first class is compiled, it has access only to the signature of the other class. Therefore, a programmer would see inconsistent results depending on whether `Client` was compiled first and had access only to the declared types of `Library`, or the `Library` was compiled first and the compiler refined the types of its methods and fields before `Client` looked them up.

Consistent behavior with or without pluggable type-checking The `.class` files produced with or without pluggable type-checking should specify the same types for all public fields and methods. If pluggable type-checking changed the those types, then users would be confused. Depending on how a library was compiled, pluggable type-checking of a client program would give different results.

34.5.4 Why doesn't the Checker Framework track relationships between variables?

The Checker Framework estimates the possible run-time value of each variable, as expressed in a type system. In general, the Checker Framework does estimate relationships between two variables, except for specific relationships listed in Section 27.8.

For example, the Checker Framework does not track which variables are equal to one another. The Nullness Checker issues a warning, “dereference of possibly-null reference y ”, for expression `y.toString()`:

```
void nullnessExample1(@Nullable Object x) {
    Object y = x;
    if (x != null) {
        System.out.println(y.toString());
    }
}
```

Code that checks one variable and then uses a different variable is confusing and is often considered poor style.

The Nullness Checker is able to verify the correctness of a small variant of the program, thanks to type refinement (Section 27.7):

```
void nullnessExample2(@Nullable Object x) {
    if (x != null) {
        Object y = x;
        System.out.println(y.toString());
    }
}
```

The difference is that in the first example, nothing was known about x at the time y was set to it, and so the Nullness Checker recorded no facts about y . In the second example, the Nullness Checker knew that x was non-null when y was assigned to it.

In the future, the Checker Framework could be enriched by tracking which variables are equal to one another, a technique called “copy propagation”.

This would handle the above examples, but wouldn't handle other examples. For example, the following code is safe:

```
void requiresPositive(@Positive int arg) {}

void intExample1(int x) {
```

```

    int y = x*x;
    if (x > 0) {
        requiresPositive(y);
    }
}

void intExample2(int x) {
    int y = x*x;
    if (y > 0) {
        requiresPositive(x);
    }
}

```

However, the Index Checker (Chapter 8, page 70), which defines the `@Positive` type qualifier, issues warnings saying that it cannot prove that the arguments are `@Positive`.

A slight variant of `intExample1` can be verified:

```

void intExample1a(int x) {
    if (x > 0) {
        int y = x*x;
        requiresPositive(y);
    }
}

```

No variant of `intExample2` can be verified. It is not worthwhile to make the Checker Framework more complex and slow by tracking rich properties such as arbitrary arithmetic.

As another example of a false positive warning due to arbitrary arithmetic properties, consider the following code:

```

void falsePositive2(int arg) {
    Object o;
    if (arg * arg >= arg) { // always true!
        o = new Object();
    }
    o.toString(); // Nullness Checker issues a false positive warning
}

```

34.5.5 Why isn't the Checker Framework path-sensitive?

The Checker Framework is not path-sensitive. That is, it maintains one estimate for each variable, and it assumes at every branch (such as `if` statement) that every choice could be taken.

In the following code, there are two `if` statements.

```

void falsePositive1(boolean b) {
    Object o;
    if (b) {
        o = new Object();
    }
    if (b) {
        o.toString(); // Nullness Checker issues a false positive warning
    }
}

```

In general, if code has two `if` statements in succession, then there are 4 possible paths through the code: `[true, true]`, `[true, false]`, `[false, true]`, and `[false, false]`. However, for this code only two of those paths are feasible: namely, `[true, true]` and `[false, false]`.

The Checker Framework is not path-sensitive, so it issues a warning.

The lack of path-sensitivity can be viewed as special case of the fact that the Checker Framework maintains a single estimate for each variable value, rather than tracking relationships between multiple variables (Section 34.5.4).

Making the Checker Framework path-sensitive would make it more powerful, but also much more complex and much slower. We have not yet found this necessary.

34.6 Syntax of type annotations

There is also a separate FAQ for the type annotations syntax (<https://checkerframework.org/jsr308/jsr308-faq.html>).

34.6.1 What is a “receiver”?

The *receiver* of a method is the `this` formal parameter, sometimes also called the “current object”. Within the method declaration, `this` is used to refer to the receiver formal parameter. At a method call, the receiver actual argument is written before a period and the method name.

The method `compareTo` takes *two* formal parameters. At a call site like `x.compareTo(y)`, the two arguments are `x` and `y`. It is desirable to be able to annotate the types of both of the formal parameters, and doing so is supported by both Java’s type annotations syntax and by the Checker Framework.

A type annotation on the receiver is treated exactly like a type annotation on any other formal parameter. At each call site, the type of the argument must be consistent with (a subtype of or equal to) the declaration of the corresponding formal parameter. If not, the type-checker issues a warning.

Here is an example. Suppose that `@A Object` is a supertype of `@B Object` in the following declaration:

```
class MyClass {
    void requiresA(@A MyClass this) { ... }
    void requiresB(@B MyClass this) { ... }
}
```

Then the behavior of four different invocations is as follows:

```
@A MyClass myA = ...;
@B MyClass myB = ...;

myA.requiresA()    // OK
myA.requiresB()    // compile-time error
myB.requiresA()    // OK
myB.requiresB()    // OK
```

The invocation `myA.requiresB()` does not type-check because the actual argument’s type is not a subtype of the formal parameter’s type.

A top-level constructor does not have a receiver. An inner class constructor does have a receiver, whose type is the same as the containing outer class. The receiver is distinct from the object being constructed. In a method of a top-level class, the receiver is named `this`. In a constructor of an inner class, the receiver is named `Outer.this` and the result is named `this`.

A method in an anonymous class has a receiver, but it is not possible to write the receiver in the formal parameter list because there is no name for the type of `this`.

34.6.2 What is the meaning of an annotation after a type, such as `@NonNull Object @Nullable`?

In a type such as `@NonNull Object @Nullable []`, it may appear that the `@Nullable` annotation is written *after* the type `Object`. In fact, `@Nullable` modifies `[]`. See the next FAQ, about array annotations (Section 34.6.3).

34.6.3 What is the meaning of array annotations such as `@NonNull Object @Nullable []`?

You should parse this as: `(@NonNull Object) (@Nullable [])`. Each annotation precedes the component of the type that it qualifies.

Thus, `@NonNull Object @Nullable []` is a possibly-null array of non-null objects. Note that the first token in the type, “`@NonNull`”, applies to the element type `Object`, not to the array type as a whole. The annotation `@Nullable` applies to the array `[]`.

Similarly, `@Nullable Object @NonNull []` is a non-null array of possibly-null objects.

Some older tools have inconsistent semantics for annotations on array and varargs elements. Their semantics is unfortunate and confusing; developers should convert their code to use type annotations instead. Section 29.1.1 explains how the Checker Framework handles declaration annotations in the meanwhile.

34.6.4 What is the meaning of varargs annotations such as `@English String @NonEmpty ...`?

Varargs annotations are treated similarly to array annotations. (A way to remember this is that when you write a varargs formal parameter such as `void method(String... x) {}`, the Java compiler generates a method that takes an array of strings; whenever your source code calls the method with multiple arguments, the Java compiler packages them up into an array before calling the method.)

Either of these annotations

```
void method(String @NonEmpty [] x) {}
void method(String @NonEmpty ... x) {}
```

applies to the array: the method takes a non-empty array of strings, or the varargs list must not be empty.

Either of these annotations

```
void method(@English String [] x) {}
void method(@English String ... x) {}
```

. applies to the element type. The annotation documents that the method takes an array of English strings.

34.6.5 What is the meaning of a type qualifier at a class declaration?

See Section 27.3.

34.6.6 How are type qualifiers written on upper and lower bounds?

See Section 26.1.2.

34.6.7 Why shouldn't a qualifier apply to both types and declarations?

It is bad style for an annotation to apply to both types and declarations. In other words, every annotation should have a `@Target` meta-annotation, and the `@Target` meta-annotation should list either only declaration locations or only type annotations. (It's OK for an annotation to target both `ElementType.TYPE_PARAMETER` and `ElementType.TYPE_USE`, but no other declaration location along with `ElementType.TYPE_USE`.)

Sometimes, it may seem tempting for an annotation to apply to both type uses and (say) method declarations. Here is a hypothetical example:

“Each `Widget` type may have a `@Version` annotation. I wish to prove that versions of widgets don’t get assigned to incompatible variables, and that older code does not call newer code (to avoid problems when backporting).

A `@Version` annotation could be written like so:

```
@Version("2.0") Widget createWidget(String value) { ... }
```

`@Version("2.0")` on the method could mean that the `createWidget` method only appears in the 2.0 version. `@Version("2.0")` on the return type could mean that the returned `Widget` should only be used by code that uses the 2.0 API of `Widget`. It should be possible to specify these independently, such as a 2.0 method that returns a value that allows the 1.0 API method invocations.”

Both of these are type properties and should be specified with type annotations. No method annotation is necessary or desirable. The best way to require that the receiver has a certain property is to use a type annotation on the receiver of the method. (Slightly more formally, the property being checked is compatibility between the annotation on the type of the formal parameter receiver and the annotation on the type of the actual receiver.) If you do not know what “receiver” means, see Section 34.6.1.

Another example of a type-and-declaration annotation that represents poor design is JCIP’s `@GuardedBy` annotation [GPB⁺06]. As discussed in Section 7.6.1, it means two different things when applied to a field or a method. To reduce confusion and increase expressiveness, the Lock Checker (see Chapter 7) uses the `@Holding` annotation for one of these meanings, rather than overloading `@GuardedBy` with two distinct meanings.

A final example of a type-and-declaration annotation is some `@Nullable` or `@NonNull` annotations that are intended to work both with modern tools that process type annotations and with old tools that were written before Java had type annotations. Such type-and-declaration annotations were a temporary measure, intended to be used until the tool supported Java 8, and should not be necessary any longer.

34.6.8 How do I annotate a fully-qualified type name?

If you write a fully-qualified type name in your program, then the Java language requires you to write a type annotation on the simple name part, such as

```
entity.hibernate. @Nullable User x;
```

If you try to write the type annotation before the entire fully-qualified name, such as

```
@Nullable entity.hibernate.User x; // illegal Java syntax
```

then you will get an error like one of the following:

```
error: scoping construct for static nested type cannot be annotated
error: scoping construct cannot be annotated with type-use annotation
```

34.6.9 What is the difference between type annotations and declaration annotations?

Java has two distinct varieties of annotation: type annotations and declaration annotations.

A **type annotation** can be written on any use of a **type**. It conceptually creates a new, more specific type. That is, it describes what values the type represents.

As an example, the `int` type contains these values: ..., -2, -1, 0, 1, 2, ...

The `@Positive int` type contains these values: 1, 2, ...

Therefore, `@Positive int` is a subtype of `int`.

A **declaration annotation** can be written on any **declaration** (a class, method, or variable). It describes the thing being declared, but does not describe run-time values. Here are examples of declaration annotations:

```

@Deprecated    // programmers should not use this class
class MyClass { ... }

@Override      // this method overrides a method in a supertype
void myMethod() { ... }

@SuppressWarnings(...) // compiler should not warn about the initialization expr
int myField = INITIALIZATION-EXPRESSION;

```

Here are examples that use both a declaration annotation and a type annotation:

```

@Override
@Regex String getPattern() { ... }

@GuardedBy("myLock")
@NonNull String myField;

```

Note that the type annotation describes the value, and the declaration annotation says something about the method or use of the field.

As a matter of style, declaration annotations are written on their own line, and type annotations are written directly before the type, on the same line.

34.7 Semantics of type annotations

34.7.1 How can I handle tpestate, or phases of my program with different data properties?

Sometimes, your program works in phases that have different behavior. For example, you might have a field that starts out null and becomes non-null at some point during execution, such as after a method is called. You can express this property as follows:

1. Annotate the field type as `@MonotonicNonNull`.
2. Annotate the method that sets the field as `@EnsuresNonNull("myFieldName")`. (If method `m1` calls method `m2`, which actually sets the field, then you would probably write this annotation on both `m1` and `m2`.)
3. Annotate any method that depends on the field being non-null as `@RequiresNonNull("myFieldName")`. The type-checker will verify that such a method is only called when the field isn't null — that is, the method is only called after the setting method.

You can also use a tpestate checker (see Chapter 25.17, page 145), but they have not been as extensively tested.

34.7.2 Why are explicit and implicit bounds defaulted differently?

The following two bits of code have the same semantics under Java, but are treated differently by the Checker Framework's CLIMB-to-top defaulting rules (Section 27.5.3):

```

class MyClass<T> { ... }
class MyClass<T extends Object> { ... }

```

The difference is the annotation on the upper bound of the type argument `T`. They are treated in the following way.

```

class MyClass<T>                == class MyClass<T extends @TOPTYPEANNO Object>
class MyClass<T extends Object> == class MyClass<T extends @DEFAULTANNO Object>

```

`@TOPTYPEANNO` is the top annotation in the type qualifier hierarchy. For example, for the nullness type system, the top type annotation is `@Nullable`, as shown in Figure 3.1. `@DEFAULTANNO` is the default annotation for the type system. For example, for the nullness type system, the default type annotation is `@NonNull`.

In some type systems, the top qualifier and the default are the same. For such type systems, the two code snippets shown above are treated the same. An example is the regular expression type system; see Figure 11.1.

The CLIMB-to-top rule reduces the code edits required to annotate an existing program, and it treats types written in the program consistently.

When a user writes no upper bound, as in `class C<T> { ... }`, then Java permits the class to be instantiated with any type parameter. The Checker Framework behaves exactly the same, no matter what the default is for a particular type system — and no matter whether the user has changed the default locally.

When a user writes an upper bound, as in `class C<T extends OtherClass> { ... }`, then the Checker Framework treats this occurrence of `OtherClass` exactly like any other occurrence, and applies the usual defaulting rules. Use of `Object` is treated consistently with all other types in this location and all other occurrences of `Object` in the program.

Here are some style guidelines:

- Omit the `extends` clause when possible. To indicate no constraints on type qualifiers, write `class MyClass<T>` rather than `class MyClass<T extends @TOPTYPEANNO Object>`.
- When you write an `Object` upper bound, give an explicit type annotation. That is, write `class C<T extends @DEFAULTANNO Object> { ... }` even though it is equivalent to writing `class C<T extends Object> { ... }`.

If you write just `extends Object`, then someone who is reading the code might think that it is irrelevant (which it is in plain Java). Also, some IDEs will suggest removing it.

34.7.3 Why are type annotations declared with `@Retention(RetentionPolicy.RUNTIME)`?

Annotations such as `@NonNull` are declared with `@Retention(RetentionPolicy.RUNTIME)`. In other words, these type annotations are available to tools at run time. Such run-time tools could check the annotations (like an `assert` statement), type-check dynamically-loaded code, check casts and `instanceof` operations, resolve reflection more precisely, or other tasks that we have not yet thought of. Not many such tools exist today, but the annotation designers wanted to accommodate them in the future.

`RUNTIME` retention has negligible costs (no run-time dependency, minimal increase in heap size).

For the purpose of static checking at compile time, `CLASS` retention would be sufficient. Note that `SOURCE` retention would not be sufficient, because of separate compilation: when type-checking a class, the compiler needs to read the annotations on libraries that it uses, and separately-compiled libraries are available to the compiler only as class files.

34.8 Creating a new checker

34.8.1 How do I create a new checker?

In addition to using the checkers that are distributed with the Checker Framework, you can write your own checker to check specific properties that you care about. Thus, you can find and prevent the bugs that are most important to you.

Chapter 32 gives complete details regarding how to write a checker. It also suggests places to look for more help, such as the Checker Framework API documentation (Javadoc) and the source code of the distributed checkers.

To whet your interest and demonstrate how easy it is to get started, here is an example of a complete, useful type-checker.

```
@SubtypeOf(Unqualified.class)
@Target({ElementType.TYPE_USE, ElementType.PARAMETER})
public @interface Encrypted {}
```

Section 24.2 explains this checker and tells you how to run it.

34.8.2 What properties can and cannot be handled by type-checking?

In theory, any property about a program can be expressed and checked within a type system. In practice, types are a good choice for some properties and a bad choice for others.

A type expresses the set of possible values for an expression. Therefore, types are a good choice for any property that is about variable values or provenance.

Types are a poor choice for expressing properties about timing, such as that action B will happen within 10 milliseconds of action A. Types are not good for verifying the results of calculations; for example, they could ensure that code always call an `encrypt` routine in the appropriate places, but not that the `encrypt` routine is correctly implemented. Types are not a good solution for preventing infinite loops, except perhaps in special cases.

34.8.3 Why is there no declarative syntax for writing type rules?

A type system implementer can declaratively specify the type qualifier hierarchy (Section 32.5.2) and the type introduction rules (Section 32.8). However, the Checker Framework uses a procedural syntax for specifying type-checking rules (Section 32.7). A declarative syntax might be more concise, more readable, and more verifiable than a procedural syntax.

We have not found the procedural syntax to be the most important impediment to writing a checker.

Previous attempts to devise a declarative syntax for realistic type systems have failed; see a technical paper [PAC⁺08] for a discussion. When an adequate syntax exists, then the Checker Framework can be extended to support it.

34.9 Tool questions

34.9.1 How does pluggable type-checking work?

The Checker Framework enables you to define a new type system. It finds errors, or guarantees their absence, by performing type-checking that is similar to that already performed by the Java compiler.

Type-checking examines each statement of your program in turn, one at a time.

- Expressions are processed bottom-up. Given types for each sub-expression, the type-checker determines whether the types are legal for the expression's operator and determines the type of the expression.
- An assignment is legal if the type of the right-hand side is a subtype of the declared type of the left-hand side.
- At a method call, the arguments are legal if they can be assigned to the formal parameters (this is called a "pseudo-assignment" and it follows the normal rules for assignment). The type of the method call is the declared type of the return type, where the method is declared. If the method declaration is not annotated, then a default annotation is used.
- Suppose that method `Sub.m` overrides method `Super.m`. The return type of `Sub.m` must be equal to or a subtype of the return type of `Super.m` (this is called "covariance"). The type of formal parameter `i` of `Sub.m` must be equal to or a *supertype* of the type of formal parameter `i` in `Super.m` (this is called "contravariance").

34.9.2 What classpath is needed to use an annotated library?

Suppose that you distribute a library, which contains Checker Framework annotations such as `@Nullable`. This enables clients of the library to use the Checker Framework to type-check their programs. To do so, they must have the Checker Framework annotations on their classpath, for instance by using the Checker Framework Compiler.

Clients who do not wish to perform pluggable type-checking do not need to have the Checker Framework annotations (`checker-qual.jar`) in their classpath, either when compiling or running their programs.

The JVM does not issue a link error if an annotation is not found when a class is loaded. (By contrast, the JVM does issue a link error if a superclass, or a parameter/return/field type, is not found.) Likewise, there is no problem compiling against a library even if the library's annotations are not on the classpath. These are properties of Java, and are not specific to the Checker Framework's annotations.

34.9.3 Why do `.class` files contain more annotations than the source code?

A `.class` file contains an annotation on every type, as computed by defaulting rules; see Section 27.4.

When an overridden method has a side effect annotation, the overriding method must have one too. However, if the side effect annotation is declared with the `@InheritedAnnotation` meta-annotation, the Checker Framework automatically adds the missing annotation. This is the case for most side effect annotations — these annotations are propagated from annotated libraries, such as the JDK, to your code.

34.9.4 Is there a type-checker for managing checked and unchecked exceptions?

It is possible to annotate exception types, and any type-checker built on the Checker Framework enforces that type annotations are consistent between `throw` statements and `catch` clauses that might catch them.

The Java compiler already enforces that all checked exceptions are caught or are declared to be passed through, so you would use annotations to express other properties about exceptions.

Checked exceptions are an example of a “type and effect” system, which is like a type system but also accounts for actions/behaviors such as side effects. The GUI Effect Checker (Chapter 16, page 109) is a type-and-effect system that is distributed with the Checker Framework.

34.9.5 The Checker Framework runs too slowly

Using a pluggable type-checker increases compile times by a factor of 2-5. Slow compilation speed is probably the worst thing about the Checker Framework.

If the Checker Framework is too slow for you to run on every compilation, you can run it periodically, such as in a Git commit hook or in continuous integration.

The Checker Framework team does not currently have the resources to fix performance problems, but we welcome community contributions.

Here are some reasons that the Checker Framework is so slow.

- It has to do all the same work as the compiler does, such as resolving overloading/overriding/generics and type-checking. It does so for richer, user-defined type systems whereas `javac` hard-codes one type system.
- Its implementation has some inefficiencies. For example, when running a compound or aggregate checker, it makes multiple passes over the program rather than just one.

34.10 Relationship to other tools

34.10.1 Why not just use a bug detector (like FindBugs or Error Prone)?

A pluggable type-checker is a verification tool that prevents or detects all errors of a given variety. If it issues no warnings, your code has no errors of a given variety (for details about the guarantee, see Section 2.3).

An alternate approach is to use a bug detector such as Error Prone, FindBugs [HP04, HSP05], Jlint [Art01], or PMD [Cop05], or the tools built into Eclipse (see Section 34.10.2) and IntelliJ.

A pluggable type-checker or verifier differs from a bug detector in several ways:

- A type-checker reports *all* errors in your code. If a type-checker reports no warnings, then you have a guarantee (a proof) of correctness (Section 34.4.4).
A bug detector aims to find *some* of the most obvious errors. Even if a bug detector reports no warnings, there may still be errors in your code.
- A type-checker requires you to annotate your code with type qualifiers, or to run an inference tool that does so for you. That is, it requires you to write a specification, then it verifies that your code meets its specification.
Some bug detectors do not require annotations. This means that it may be easier to get started running a bug detector. The tool makes guesses about the intended behavior of your code, leading to false alarms or missed alarms.

- A verification tool may issue more warnings for a programmer to investigate. Some bug detectors internally generate many warnings, then use heuristics to discard some of them. The cost is missed alarms, when the tool's heuristics classified the warnings as likely false positives and discarded them.
 - A type-checker uses a more sophisticated and precise analysis. For example, it can take advantage of method annotations and annotations on generic type parameters, such as `List<@NonNull String>`. An example specific to the Nullness Checker (Section 3, no other tool correctly handles map keys or initialization. A bug detector does a more lightweight analysis. This means that a bug detector usually runs faster, giving feedback to the programmer more rapidly and avoiding slowdowns. Its analysis is often narrow, avoiding properties that are tricky to reason about or that might lead to false alarms. The cost is missed alarms, when analysis is too weak to find the errors.
 - Neither type checking nor bug detection subsumes the other. A type-checker finds problems that a bug detector cannot. A bug detector finds problems that a type-checker does not: there is no need for the type-checker to address style rules, when a bug detector is adequate.
- If your code is important to you, it is advantageous to run both types of tools.

For a case study that compared the nullness analysis of FindBugs, Jlint, PMD, and the Checker Framework, see section 6 of the paper “Practical pluggable types for Java” [PAC⁺08]. The case study was on a well-tested program in daily use. The Checker Framework tool found 8 nullness errors (that is, null pointer dereferences). None of the other tools found any errors. A follow-up 10 years later found that Eclipse's and IntelliJ's nullness analyses found 0 and 3 out of the 9 errors that the Nullness Checker found.

The JSR 308 [Ern08] documentation also contains a discussion of related work.

34.10.2 How does the Checker Framework compare with Eclipse's null analysis?

Eclipse comes with a null analysis that can detect potential null pointer errors in your code. Eclipse's built-in analysis differs from the Checker Framework in several respects.

The Checker Framework's Nullness Checker (see Chapter 3, page 27) is more precise: it does a deeper semantic analysis, so it issues fewer false positives than Eclipse. Eclipse's nullness analysis is missing many features that the Checker Framework supports, such as handling of map keys, partially-initialized objects, method pre- and post-conditions, polymorphism, and a powerful dataflow analysis. These are essential for practical verification of real-world code without poor precision. Furthermore, Eclipse by default ignores unannotated code (even unannotated parameters within a method that contains other annotations). As a result, Eclipse is more useful for bug-finding than for verification, and that is what the Eclipse documentation recommends.

Eclipse assumes by default that all code is multi-threaded, which cripples its local type inference. (This default can be turned off, however.) The Checker Framework allows the user to specify whether code will be run concurrently or not via the `-AconcurrentSemantics` command-line option (see Section 34.4.5).

The Checker Framework builds on javac, so it is easier to run in integration scripts or in environments where not all developers have installed Eclipse.

Eclipse handles only nullness properties and is not extensible, whereas the Checker Framework comes with over 20 type-checkers (for a list, see Chapter 1, page 13) and is extensible to more properties.

There are also some benefits to Eclipse's null analysis. It is faster than the Checker Framework, in part because it is less featureful. It is built into Eclipse, so you do not have to add it to your build scripts. Its IDE integration is tighter and slicker.

In a case study, the Nullness Checker found 9 errors in a program, and Eclipse's analysis found 0.

34.10.3 How does the Checker Framework compare with NullAway?

NullAway is a lightweight, unsound type-checker whose aim is similar to that of the Nullness Checker (Chapter 3, page 27). For both tools, the user writes nullness annotations, and then the tool checks them.

NullAway is faster than the Nullness Checker and requires fewer annotations.

NullAway is unsound: even if NullAway issues no warnings, your code might crash with a null pointer exception. Two differences are that NullAway makes unchecked assumptions about getter methods and NullAway assumes all

objects are always fully initialized. NullAway forces all generic arguments to be non-null, which is not an unsoundness but is less flexible than the Nullness Checker.

34.10.4 How does the Checker Framework compare with the JDK's `Optional` type?

JDK 8 introduced the `Optional` class, a container that is either empty or contains a non-null value. The `Optional` Checker (see Chapter 5) guarantees that programmers use `Optional` correctly.

Section 3.7.3 explains the relationship between nullness and `Optional` and the benefits of each.

34.10.5 How does pluggable type-checking compare with JML?

JML, the Java Modeling Language [LBR06], is a language for writing formal specifications.

JML aims to be more expressive than pluggable type-checking. A programmer can write a JML specification that describes arbitrary facts about program behavior. Then, the programmer can use formal reasoning or a theorem-proving tool to verify that the code meets the specification. Run-time checking is also possible. By contrast, pluggable type-checking can express a more limited set of properties about your program. Pluggable type-checking annotations are more concise and easier to understand.

JML is not as practical as pluggable type-checking. The JML toolset is less mature. For instance, if your code uses generics or other features of Java 5, then you cannot use JML. However, JML has a run-time checker, which the Checker Framework currently lacks.

34.10.6 Is the Checker Framework an official part of Java?

The Checker Framework is not an official part of Java. The Checker Framework relies on type annotations, which are part of Java 8. See the Type Annotations (JSR 308) FAQ for more details.

34.10.7 What is the relationship between the Checker Framework and JSR 305?

JSR 305 aimed to define official Java names for some annotations, such as `@NonNull` and `@Nullable`. However, it did not aim to precisely define the semantics of those annotations nor to provide a reference implementation of an annotation processor that validated their use; as a result, JSR 305 was of limited utility as a specification. JSR 305 has been abandoned; there has been no activity by its expert group since 2009.

By contrast, the Checker Framework precisely defines the meaning of a set of annotations and provides powerful type-checkers that validate them. However, the Checker Framework is not an official part of the Java language; it chooses one set of names, but another tool might choose other names.

In the future, the Java Community Process might revitalize JSR 305 or create a replacement JSR to standardize the names and meanings of specific annotations, after there is more experience with their use in practice.

The Checker Framework defines annotations `@NonNull` and `@Nullable` that are compatible with annotations defined by JSR 305, FindBugs, IntelliJ, and other tools; see Section 3.7.

34.10.8 What is the relationship between the Checker Framework and JSR 308?

JSR 308, also known as the Type Annotations specification, dictates the syntax of type annotations in Java SE 8: how they are expressed in the Java language.

JSR 308 does not define any type annotations such as `@NonNull`, and it does not specify the semantics of any annotations. Those tasks are left to third-party tools. The Checker Framework is one such tool.

Chapter 35

Troubleshooting, getting help, and contributing

The manual might already answer your question, so first please look for your answer in the manual, including this chapter and the FAQ (Chapter 34). If not, you can use the mailing list, `checker-framework-discuss@googlegroups.com`, to ask other users for help. For archives and to subscribe, see <https://groups.google.com/forum/#!forum/checker-framework-discuss>. To report bugs, please see Section 35.2. If you want to help out, you can give feedback (including on the documentation), choose a bug and fix it, or select a project from the ideas list at <https://rawgit.com/typetools/checker-framework/master/docs/developer/gsoc-ideas.html>.

35.1 Common problems and solutions

- To verify that you are using the compiler you think you are, you can add `-version` to the command line. For instance, instead of running `javac -g MyFile.java`, you can run `javac -version -g MyFile.java`. Then, `javac` will print out its version number in addition to doing its normal processing.

35.1.1 Unable to compile the Checker Framework

If you get the following error while compiling the Checker Framework itself:

```
checker-framework/stubparser/dist/stubparser.jar(org/checkerframework/stubparser/ast/CompilationUnit.class):  
warning: [classfile] Signature attribute introduced in version 49.0 class files is ignored in version 46.0 class files
```

and you have used Eclipse to compile the Checker Framework, then probably you are using a very old version of Eclipse. (If you install Eclipse from the Ubuntu 16.04 repository, you get Eclipse version 3.8. Ubuntu 16.04 was released in April 2016, and Eclipse 3.8 was released in June 2012, with subsequent major releases in June 2013, June 2014, and June 2015.) Install the latest version of Eclipse and use it instead.

35.1.2 Unable to run the checker, or checker crashes

If you are unable to run the checker, or if the checker or the compiler terminates with an error, then the problem may be a problem with your environment. (If the checker or the compiler crashes, that is a bug in the Checker Framework; please report it. See Section 35.2.) This section describes some possible problems and solutions.

- An error that includes `java.lang.NoSuchFieldError: "RELEASE"` means that you are not using the correct compiler (you are not using a Java 9+ compiler).
- If you get the error

```
com.sun.tools.javac.code.Symbol$CompletionFailure: class file for com.sun.source.tree.Tree not found
```

then you are using the source installation and file `tools.jar` is not on your classpath. See the installation instructions (Section 1.3).

- If you get an error like one of the following,

```
...\build.xml:59: Error running ${env.CHECKERFRAMEWORK}\checker\bin\javac.bat compiler
.../bin/javac: Command not found
```

then the problem may be that you have not set the `CHECKERFRAMEWORK` environment variable, as described in Section 33.5. Or, maybe you made it a user variable instead of a system variable.

- If you get one of these errors:

The hierarchy of the type `ClassName` is inconsistent

The type `com.sun.source.util.AbstractTypeProcessor` cannot be resolved.

It is indirectly referenced from required `.class` files

then you are likely **not** using the Checker Framework compiler. Use either `$CHECKERFRAMEWORK/checker/bin/javac` or one of the alternatives described in Section 33.5.

- If you get the error

```
java.lang.ArrayStoreException: sun.reflect.annotation.TypeNotPresentExceptionProxy
```

then an annotation is not present at run time that was present at compile time. For example, maybe when you compiled the code, the `@Nullable` annotation was available, but it was not available at run time. You can use JDK 8 at run time.

- If you get an error that contains lines like these:

```
Caused by: java.util.zip.ZipException: error in opening zip file
    at java.util.zip.ZipFile.open(Native Method)
    at java.util.zip.ZipFile.<init>(ZipFile.java:131)
```

then one possibility is that you have installed the Checker Framework in a directory that contains special characters that Java's `ZipFile` implementation cannot handle. For instance, if the directory name contains "+", then Java 1.6 throws a `ZipException`, and Java 1.7 throws a `FileNotFoundException` and prints out the directory name with "+" replaced by blanks.

- The Checker Framework sometimes runs out of memory when processing very large Java files, or files with very large methods.

If you get an error such as

```
error: SourceChecker.typeProcess: unexpected Throwable (OutOfMemoryError) while processing ...; messa
```

then either give the JVM more memory when running the Checker Framework, or split your files and methods into smaller ones, or both.

- Error Prone uses the Checker Framework's dataflow analysis library. Unfortunately, Error Prone uses an old version of the library, so you cannot use both Error Prone and the current Checker Framework (because each one depends on a different version of the dataflow library).

Until the Error Prone tool is fixed, you can use an older version of the Checker Framework (the one that Error Prone is built on), or you can use a switch that causes your build to use either Error Prone or the Checker Framework, but not both. The Gradle plugin documentation (<https://github.com/kellogg/checkerframework-gradle-plugin#incompatibility-with-error-prone>) shows how to do the latter for Gradle.

35.1.3 Unexpected warnings not related to type-checking

This section gives solutions for some warning messages that are not related to type errors in your code.

- If you get an error like the following

```
error: scoping construct for static nested type cannot be annotated
error: scoping construct cannot be annotated with type-use annotation
```

then you have probably written something like one of the following:

@Nullable java.util.List The correct Java syntax to write an annotation on a fully-qualified type name is to put the annotation on the simple name part, as in `java.util.@Nullable List`. But, it's usually better to add `import java.util.List` to your source file, so that you can just write `@Nullable List`.

@Nullable Map.Entry You must write `Outer.@Nullable StaticNestedClass` rather than `@Nullable Outer.StaticNestedClass`. Since a static nested class does not depend on its outer class, the annotation on the outer class would have no effect and is forbidden.

Java 8 requires that a type qualifier be written directly on the type that it qualifies, rather than on a scoping mechanism that assists in resolving the name. Examples of scoping mechanisms are package names and outer classes of static nested classes.

The reason for the Java 8 syntax is to avoid syntactic irregularity. When writing a member nested class (also known as an inner class), it is possible to write annotations on both the outer and the inner class: `@A1 Outer. @A2 Inner`. Therefore, when writing a static nested class, the annotations should go on the same place: `Outer. @A3 StaticNested` (rather than `@ConfusingAnnotation Outer. Nested` where `@ConfusingAnnotation` applies to `Outer` if `Nested` is a member class and applies to `Nested` if `Nested` is a static class). It's not legal to write an annotation on the outer class of a static nested class, because neither annotations nor instantiations of the outer class affect the static nested class.

Similar arguments apply when annotating `package.Outer.Nested`.

- An “error: package ... does not exist” or “error: cannot find symbol” about classes in your own project or its dependencies means that you have left your own project or its dependencies off the classpath when you invoked the compiler.

35.1.4 Unexpected type-checking results

This section describes possible problems that can lead the type-checker to give unexpected results.

- If the Checker Framework is unable to verify a property that you know is true, then you should formulate a proof about why the property is true. Your proof depends on some set of facts about the program and its operation. State them completely; for example, don't write “the field `f` cannot be null when execution reaches line 22”, but justify *why* the field cannot be null.

Once you have written down your proof, translate each fact into a Java annotation.

If you are unable to express some aspect of your proof as an annotation, then the type system is not capable of reproducing your proof. You might need to find a different proof, or extend the type system to be more expressive, or suppress the warning.

If you are able to express your entire proof as annotations, then look at the Checker Framework error messages. One possibility is that the errors indicate that your proof was incomplete or incorrect. Maybe your proof implicitly depended on some fact you didn't write down, such as “method `m` has no side effects.” In this case, you should revise your proof and add more annotations to your Java code. Another possibility is that your proof is incorrect, and the errors indicate where. Another possibility is that there is a bug in the type-checker. In this case, you should report it to the maintainers, giving your proof and explaining why the type-checker should be able to make the same inferences that you did.

Recall that the Checker Framework does modular verification, one procedure at a time; it observes the specifications, but not the implementations, of other methods.

Also see Section 2.4.5, which explains this same methodology in different words.

- If a checker seems to be ignoring the annotation on a method, then it is possible that the checker is reading the method's signature from its `.class` file, but the `.class` file was not created by a Java 8 or later compiler. You can check whether the annotations actually appear in the `.class` file by using the `javap` tool.

If the annotations do not appear in the `.class` file, here are two ways to solve the problem:

- Re-compile the method's class with the Checker Framework compiler. This will ensure that the type annotations are written to the class file, even if no type-checking happens during that execution.

- Pass the method’s file explicitly on the command line when type-checking, so that the compiler reads its source code instead of its .class file.
- If a checker issues a warning about a property that it accepted (or that was checked) on a previous line, then probably there was a side-effecting method call in between that could invalidate the property. For example, in this code:

```
if (currentOutgoing != null && !message.isCompleted()) {
    currentOutgoing.continueBuffering(message);
}
```

the Nullness Checker will issue a warning on the second line:

```
warning: [dereference.of.nullable] dereference of possibly-null reference currentOutgoing
    currentOutgoing.continueBuffering(message);
    ^
```

If `currentOutgoing` is a field rather than a local variable, and `isCompleted()` is not a pure method, then a null pointer dereference can occur at the given location, because `isCompleted()` might set the field `currentOutgoing` to null.

If you want to communicate that `isCompleted()` does not set the field `currentOutgoing` to null, you can use `@Pure`, `@SideEffectFree`, or `@EnsuresNonNull` on the declaration of `isCompleted()`; see Sections 27.7.5 and 3.2.2.

- If a checker issues a type-checking error for a call that the library’s documentation states is correct, then maybe that library method has not yet been annotated, so default annotations are being used.

To solve the problem, add the missing annotations to the library (see Chapter 31). The annotations might appear in stub files (which appear in an .astub file together with the checker’s source code) or in the form of annotated libraries (which appear in <https://github.com/typetools/>).

- If the compiler reports that it cannot find a method from the JDK or another external library, then maybe the stub file for that class is incomplete.

To solve the problem, add the missing annotations to the library, as described in the previous item.

The error might take one of these forms:

```
method sleep in class Thread cannot be applied to given types
cannot find symbol: constructor StringBuffer(StringBuffer)
```

- If you get an error related to a bounded type parameter and a literal such as `null`, the problem may be missing defaulting. Here is an example:

```
mypackage/MyClass.java:2044: warning: incompatible types in assignment.
    T retval = null;
        ^
    found   : null
    required: T extends @MyQualifier Object
```

A value that can be assigned to a variable of type `T extends @MyQualifier Object` only if that value is of the bottom type, since the bottom type is the only one that is a subtype of every subtype of `T extends @MyQualifier Object`. The value `null` satisfies this for the Java type system, and it must be made to satisfy it for the pluggable type system as well. The typical way to address this is to call `addStandardLiteralQualifiers` on the `LiteralTreeAnnotator`.

- An error such as

```
MyFile.java:123: error: incompatible types in argument.
    myModel.addElement("Scanning directories...");
                   ^
    found   : String
    required: ? extends Object
```

may stem from use of raw types. (“String” might be a different type and might have type annotations.) If your declaration was

```
DefaultListModel myModel;
```

then it should be

```
DefaultListModel<String> myModel;
```

Running the regular Java compiler with the `-Xlint:unchecked` command-line option will help you to find and fix problems such as raw types.

- The error

```
error: annotation type not applicable to this kind of declaration
... List<@NonNull String> ...
```

indicates that you are using a definition of `@NonNull` that is a declaration annotation, which cannot be used in that syntactic location. For example, many legacy annotations such as those listed in Figure 3.2 are declaration annotations. You can fix the problem by instead using a definition of `@NonNull` that is a type annotation, such as the Checker Framework's annotations; often this only requires changing an `import` statement.

- If Eclipse gives the warning

```
The annotation @NonNull is disallowed for this location
```

then you have the wrong version of the `org.eclipse.jdt.annotation` classes. Eclipse includes two incompatible versions of these annotations. You want the one with a name like `org.eclipse.jdt.annotation_2.0.0....jar`, which you can find in the `plugins` subdirectory under the Eclipse installation directory. Add this `.jar` file to your build path.

- When one formal parameter's annotation references another formal parameter's name, as in this constructor:

```
public String(char value[], @IndexFor("value") int offset, @IndexOrHigh("value") int count) { ... }
```

you will get an error such as

```
[expression.unparsable.type.invalid] Expression in dependent type annotation invalid:
Use "#1" rather than "value"
```

Section 27.8 explains that you need to use a different syntax to refer to a formal parameter:

```
public String(char value[], @IndexFor("#1") int offset, @IndexOrHigh("#1") int count) { ... }
```

35.1.5 Unexpected compilation output when running javac without a pluggable type-checker

A message of the form

```
error: annotation values must be of the form 'name=value'
    @LTLengthOf("firstName", "lastName") int index;
                ^
```

is caused by incorrect Java syntax. When you supply a set of multiple values as an annotation argument, you need to put curly braces around them:

```
@LTLengthOf({"firstName", "lastName"}) int index;
```

A message of the form

```
Error: cannot find symbol
```

for an annotation type that is imported, and is applied to a statically-imported enum, is caused by a javac bug, unrelated to the Checker Framework. See <https://bugs.openjdk.java.net/browse/JDK-7101822> and <https://bugs.openjdk.java.net/browse/JDK-8169095>.

35.2 How to report problems (bug reporting)

If you have a problem with any checker, or with the Checker Framework, please file a bug at <https://github.com/typetools/checker-framework/issues>. (First, check whether there is an existing bug report for that issue.) If the problem is with an incorrect or missing annotation on a library, including the JDK, see Section 35.2.1.

Alternately (especially if your communication is not a bug report), you can send mail to checker-framework-dev@googlegroups.com. We welcome suggestions, annotated libraries, bug fixes, new features, new checkers, and other improvements.

Please ensure that your bug report is clear and that it is complete. Otherwise, we may be unable to understand it or to reproduce it, either of which would prevent us from helping you. Your bug report will be most helpful if you:

- Add `-version -verbose -AprintAllQualifiers` to the javac options. This causes the compiler to output debugging information, including its version number.
- Indicate exactly what you did. Don't skip any steps, and don't merely describe your actions in words. Show the exact commands by attaching a file or using cut-and-paste from your command shell. Always include plaintext, not just a screenshot. Try to reproduce the problem from the command line as well as from an IDE or within a build system; that helps to indicate whether the problem is with the IDE or build system.
- Include all files that are necessary to reproduce the problem. This includes every file that is used by any of the commands you reported, and possibly other files as well. Please attach the files, rather than pasting their contents into the body of your bug report or email message, because some mailers mangle formatting of pasted text. If you encountered a problem while using tool integration such as Maven integration, then try to reproduce the problem from the command line as well — this will indicate whether the problem is with the checker itself or with the tool integration. If you use an invasive annotation processor such as Lombok, then try to reproduce the problem without it — this will indicate whether the problem is in the Checker Framework proper or in its interaction with Lombok. If you cannot share your code, create a new, small test case. (This is helpful even if your code is not secret!) The progress tracing options (Section 32.12.4) can be helpful in determining which file the Checker Framework was processing when it crashed.
- Indicate exactly what the result was by attaching a file or using cut-and-paste from your command shell (don't merely describe it in words, don't use a screenshot, and don't provide just part of the output).
- If the problem is not a crash, then indicate what you expected the result to be, since a bug is a difference between desired and actual outcomes. Also, please indicate **why** you expected that result — explaining your reasoning can help you understand how your reasoning is different than the checker's and which one is wrong. Remember that the checker reasons modularly and intraprocedurally: it examines one method at a time, using only the method signatures of other methods.
- Indicate what you have already done to try to understand the problem. Did you do any additional experiments? What parts of the manual did read, and what else did you search for in the manual? Without this information, the maintainers may give you redundant suggestions.

A particularly useful format for a test case is as a new file, or a diff to an existing file, for the existing Checker Framework test suite. For instance, for the Nullness Checker, see directory `checker-framework/checker/tests/nullness/`. But, please report your bug even if you do not report it in this format.

When reporting bugs, please focus on realistic scenarios and well-written code. We are sure that you can make up artificial code that stymies the type-checker! Those aren't a good use of your time to report nor the maintainers' time to evaluate and fix.

35.2.1 Problems with annotated libraries

If a checker reports a warning because a library contains *incorrect* annotations, then please open a pull request that adds the annotations. If the library's maintainers have added annotations, make a pull request to them. If the Checker Framework maintainers have added annotations, you can find the annotated source in <https://github.com/typetools/>.

If a checker reports a warning because a library is *not annotated*, please do not open a GitHub issue. Instead, we appreciate pull requests to help us improve the annotations. Alternatively or in the interim, you can use stub files as described in Section 31.5.

For either approach, please see Chapter 31, page 184 for tips about writing library annotations.

Thanks for your contribution to the annotated libraries!

35.3 Building from source

The Checker Framework release (Section 1.3) contains everything that most users need, both to use the distributed checkers and to write your own checkers. This section describes how to compile its binaries from source. You will be using the latest development version of the Checker Framework, rather than an official release.

Note the JDK requirements (Section 1.3).

35.3.1 Install prerequisites

You need to install several packages in order to build the Checker Framework. Follow the instructions for your operating system. If your OS is not listed, adapt the instructions for an existing OS; for example, other Linux distributions will be similar to Ubuntu.

Ubuntu Run the following commands:

```
sudo apt-get -qqy update
sudo apt-get -qqy install \
  openjdk-11-jdk \
  ant cpp git gradle jq libcurl3-gnutls \
  make maven mercurial python3-pip python3-requests unzip wget \
  dia hevea imagemagick latexmk librsvg2-bin maven rsync \
  texlive-font-utils texlive-fonts-recommended \
  texlive-latex-base texlive-latex-extra texlive-latex-recommended
pip3 install html5validator
```

You may have to answer questions about which time zone your computer is in.

Mac OS If you employ homebrew to install packages, run the following commands:

```
brew update
brew install git ant hevea maven mercurial librsvg unzip make
brew cask install java
brew cask install mactex
```

Make a latex directory and copy hevea.sty file into it (you may need to update the version number 2.31):

```
mkdir -p $HOME/Library/texmf/tex/latex
cp -p /usr/local/Cellar/hevea/2.31/lib/hevea/hevea.sty $HOME/Library/texmf/tex/latex/
```

Note: If copy permission is denied, try sudo.

Also set the JAVA_HOME environment variable in your .bashrc file; for example,

```
export JAVA_HOME=/Library/Java/JavaVirtualMachines/jdk1.8.0_144.jdk/Contents/Home
```

Windows To build on Windows 10, run bash to obtain a version of Ubuntu (provided by the Windows Subsystem for Linux) and follow the Ubuntu instructions.

35.3.2 Obtain the source

Obtain the latest source code from the version control repository:

```
git clone https://github.com/typetools/checker-framework.git checker-framework
export CHECKERFRAMEWORK='pwd'/checker-framework
```

You might want to add an `export CHECKERFRAMEWORK=...` line to your `.bashrc` file.

Set the `JAVA_HOME` environment variable to the location of your JDK 8 or JDK 11 installation (not the JRE installation, and not JDK 7 or earlier). (The `JAVA_HOME` environment variable might already be set, because it is needed for Ant to work.)

Ubuntu If you use the bash shell, put the following command in your `.bashrc` file. (This might not work if `java` refers to an executable in the JRE rather than in the JDK, but you need the JDK installed to build the Checker Framework anyway.)

```
export JAVA_HOME=${JAVA_HOME:-$(dirname $(dirname $(dirname $(readlink -f $(/usr/bin/which java))))))}
```

Mac OS X 10.5 or later Add one of the following two commands in your `.bash_profile` or `.profile` file according to the version of your JDK.

```
export JAVA_HOME=$(/usr/libexec/java_home -v 1.8)
export JAVA_HOME=$(/usr/libexec/java_home -v 1.9)
```

35.3.3 Build the Checker Framework

1. Run `./gradlew cloneAndBuildDependencies` to build the Checker Framework dependencies:

```
cd $CHECKERFRAMEWORK
./gradlew cloneAndBuildDependencies
```

2. Run `./gradlew assemble` to build the Checker Framework:

```
cd $CHECKERFRAMEWORK
./gradlew assemble
```

3. Once it is built, you may wish to put the Checker Framework's `javac` even earlier in your `PATH`:

```
export PATH=$CHECKERFRAMEWORK/checker/bin:${PATH}
```

The Checker Framework's `javac` ensures that all required libraries are on your classpath and boot classpath, but is otherwise identical to the Type Annotations compiler.

Putting the Checker Framework's `javac` earlier in your `PATH` will ensure that the Checker Framework's version is used.

4. If you are developing a checker within the Checker Framework, there is a developer version of `javac` in the `bin-devel` directory. This version will use compiled classes from `dataflow/build`, `javacutil/build`, `framework/build`, and `checker/build` in the `checker-framework` directory instead of the compiled jar files, and by default will print stack traces for all errors.

To use it, set your `PATH` to use `javac` in the `bin-devel` directory:

```
export PATH=$CHECKERFRAMEWORK/checker/bin-devel:${PATH}
```

The developer version of `javac` allows you to not have to rebuild the jar files after every code change, in turn allowing you to test your changes faster. Source files can be compiled using command `./gradlew compileJava`, or can be automatically compiled by an IDE such as Eclipse.

5. Test that everything works:

- Run `./gradlew allTests`:

```
cd $CHECKERFRAMEWORK
./gradlew allTests
```

- Run the Nullness Checker examples (see Section 3.5, page 34).

35.3.4 Build the Checker Framework Manual (this document)

1. Install needed packages; see Section 35.3.1 for instructions.
2. Run `make` in the `docs/manual` directory to build both the PDF and HTML versions of the manual.

35.3.5 Code style, IDE configuration, pull requests, etc.

Please see the Checker Framework Developer Manual.

35.3.6 Enable continuous integration builds

We strongly recommend that you enable continuous integration (CI) builds on your fork of the projects, so that you learn quickly about errors. See the CI instructions in the Checker Framework Developer Manual.

If you make a change to the annotated JDK, you need to upload a JDK artifact. Follow the instructions at <https://github.com/typetools/annotated-libraries>.

Debugging continuous integration builds

If a continuous integration job is failing, you can reproduce the problem locally. The CI jobs all run within Docker containers. Install Docker on your local computer, then perform commands like the following to get a shell within Docker:

```
docker pull mdernst/cf-ubuntu-jdk8
docker run -it mdernst/cf-ubuntu-jdk8 /bin/bash
```

Then, you can run arbitrary commands, including those that appear in the CI configuration files.

35.4 Contributing fixes (creating a pull request)

Please see the pull requests section of the Developer Manual. Thanks in advance for your contributions!

35.5 Publications

Here are two technical papers about the Checker Framework itself:

- “Practical pluggable types for Java” [PAC⁺08] (ISSTA 2008, <https://homes.cs.washington.edu/~mernst/pubs/pluggable-checkers-issta2008.pdf>) describes the design and implementation of the Checker Framework. The paper also describes case studies in which the Nullness, Interning, Javari, and IGJ Checkers found previously-unknown errors in real software. The case studies also yielded new insights about type systems.
- “Building and using pluggable type-checkers” [DDE⁺11] (ICSE 2011, <https://homes.cs.washington.edu/~mernst/pubs/pluggable-checkers-icse2011.pdf>) discusses further experience with the Checker Framework, increasing the number of lines of verified code to 3 million. The case studies are of the Fake Enum, Signature String, Interning, and Nullness Checkers. The paper also evaluates the ease of pluggable type-checking with the Checker Framework: type-checkers were easy to write, easy for novices to use, and effective in finding errors.

Here are some papers about type systems that were implemented and evaluated using the Checker Framework:

Nullness (Chapter 3) See the two papers about the Checker Framework, described above.

Rawness initialization (Section 25.8) “Inference of field initialization” (ICSE 2011, <https://homes.cs.washington.edu/~mernst/pubs/initialization-icse2011-abstract.html>) describes inference for the Rawness Initialization Checker.

Interning (Chapter 6) See the two papers about the Checker Framework, described above.

Locking (Chapter 7) “Locking discipline inference and checking” (ICSE 2016, <https://homes.cs.washington.edu/~mernst/pubs/locking-inference-checking-icse2016-abstract.html>) describes the Lock Checker.

Fake enumerations, type aliases, and typedefs (Chapter 9) See the ICSE 2011 paper about the Checker Framework, described above.

Regular expressions (Chapter 11) “A type system for regular expressions” [SDE12] (FTfJP 2012, <https://homes.cs.washington.edu/~mernst/pubs/regex-types-ftfjp2012-abstract.html>) describes the Regex Checker.

Format Strings (Chapter 12) “A type system for format strings” [WKSE14] (ISSTA 2014, <https://homes.cs.washington.edu/~mernst/pubs/format-string-istta2014-abstract.html>) describes the Format String Checker.

Signature strings (Chapter 15) See the ICSE 2011 paper about the Checker Framework, described above.

GUI Effects (Chapter 16) “JavaUI: Effects for controlling UI object access” [GDEG13] (ECOOP 2013, <https://homes.cs.washington.edu/~mernst/pubs/gui-thread-ecoop2013-abstract.html>) describes the GUI Effect Checker.

“Verification games: Making verification fun” (FTfJP 2012, <https://homes.cs.washington.edu/~mernst/pubs/verigames-ftfjp2012-abstract.html>) describes a general inference approach that, at the time, had only been implemented for the Nullness Checker (Section 3).

Thread locality (Section 25.15) “Loci: Simple thread-locality for Java” [WPM⁺09] (ECOOP 2009, <http://janvitek.org/pubs/ecoop09.pdf>)

Security (Section 25.10) “Static analysis of implicit control flow: Resolving Java reflection and Android intents” [BJM⁺15] (ASE 2015, <https://homes.cs.washington.edu/~mernst/pubs/implicit-control-flow-ase2015-abstract.html>) describes the SPARTA toolset and information flow type-checker.

“Boolean formulas for the static identification of injection attacks in Java” [ELM⁺15] (LPAR 2015, <https://homes.cs.washington.edu/~mernst/pubs/detect-injections-lpar2015-abstract.html>)

Generic Universe Types (Section 25.13) “Tunable static inference for Generic Universe Types” (ECOOP 2011, <https://homes.cs.washington.edu/~mernst/pubs/tunable-typeinf-ecoop2011-abstract.html>) describes inference for the Generic Universe Types type system.

Another implementation of Universe Types and ownership types is described in “Inference and checking of object ownership” [HDME12] (ECOOP 2012, <https://homes.cs.washington.edu/~mernst/pubs/infer-ownership-ecoop2012.html>).

Approximate data (Section 25.12) “EnerJ: Approximate Data Types for Safe and General Low-Power Computation” [SDF⁺11] (PLDI 2011, <https://homes.cs.washington.edu/~luisceze/publications/Enerj-pldi2011.pdf>)

Information flow and tainting (Section 25.10) “Collaborative Verification of Information Flow for a High-Assurance App Store” [EJM⁺14] (CCS 2014, <https://homes.cs.washington.edu/~mernst/pubs/infoflow-ccs2014.pdf>) describes the SPARTA information flow type system.

IGJ and OIGJ immutability (Section 25.9) “Object and reference immutability using Java generics” [ZPA⁺07] (ES-EC/FSE 2007, <https://homes.cs.washington.edu/~mernst/pubs/immutability-generics-fse2007-abstract.html>) and “Ownership and immutability in generic Java” [ZPL⁺10] (OOPSLA 2010, <https://homes.cs.washington.edu/~mernst/pubs/ownership-immutability-oopsla2010-abstract.html>) describe the IGJ and OIGJ immutability type systems. For further case studies, also see the ISSTA 2008 paper about the Checker Framework, described above.

Javari immutability (Section 25.9) “Javari: Adding reference immutability to Java” [TE05] (OOPSLA 2005, <https://homes.cs.washington.edu/~mernst/pubs/ref-immutability-oopsla2005-abstract.html>) describes the Javari type system. For inference, see “Inference of reference immutability” [QTE08] (ECOOP 2008, <https://homes.cs.washington.edu/~mernst/pubs/infer-refimmutability-ecoop2008-abstract.html>) and “Parameter reference immutability: Formal definition, inference tool, and comparison” [AQKE09] (J.ASE 2009, <https://homes.cs.washington.edu/~mernst/pubs/mutability-jase2009-abstract.html>). For further case studies, also see the ISSTA 2008 paper about the Checker Framework, described above.

ReIm immutability “ReIm & ReImInfer: Checking and inference of reference immutability and method purity” [HMDE12] (OOPSLA 2012, <https://homes.cs.washington.edu/~mernst/pubs/infer-refimmutability-oopsla2012-abstract.html>) describes the ReIm immutability type system.

In addition to these papers that discuss use the Checker Framework directly, other academic papers use the Checker Framework in their implementation or evaluation. Most educational use of the Checker Framework is never published, and most commercial use of the Checker Framework is never discussed publicly.

(If you know of a paper or other use that is not listed here, please inform the Checker Framework developers so we can add it.)

35.6 Credits and changelog

Differences from previous versions of the checkers and framework can be found in the `changelog.txt` file. This file is included in the Checker Framework distribution and is also available on the web at <https://checkerframework.org/changelog.txt>.

Developers who have contributed code to the Checker Framework include Abraham Lin, Akash Srivastava, Alvin Abdagic, Anant Jain, Anatoly Kupriyanov, Andy Turner, Arie van Deursen, Arthur Baars, Ashish Rana, Asumu Takikawa, Atul Dada, Ayush Agarwal, Baorui Zhou, Basil Peace, Benno Stein, Bohdan Sharipov, Brian Corcoran, Calvin Loncaric, Charles Chen, Charlie Garrett, Chris Povirk, Christopher Mackie, Colin S. Gordon, Dan Brotherston, Dan Brown, David Lazar, David McArthur, Dilraj Singh, Eric Spishak, Felipe R. Monteiro, Gautam Korlam, Google Inc. (via @wmdietlGC), Haaris Ahmed, Heath Borders, Jakub Vrána, Javier Thaine, Jeff Luo, Jenny Xiang, Jianchu Li, Jiangqi Zhang, Jiasen (Jason) Xu, Joe Schafer, John Vandenberg, Jonathan Burke, Jonathan Nieder, Kartikeya Goswami, Kivanc Muslu, Konstantin Weitz, Liam Miller-Cushon, Lian Sun, Luqman Aden, Lázaro Clapp, Mahmood Ali, Manu Sridharan, Mark Roberts, Martin Kelloog, Matt Mullen, Maximilian Gama, Michael Bayne, Michael Coblenz, Michael Ernst, Michael Hixson, Michael Sloan, Mier Ta, Mrigank Arora, Nhat Dinh, Nhat Nguyen, Nikhil Shinde, Nima Karimipour, Oleg Shchelykhalnov, Pascal Wittmann, Patrick Meiring, Paul Vines, Paulo Barros, Philip Lai, Prionti Nasir, Rashmi Mudduluru, Ravi Roshan, Renato Athaydes, René Just, Raturaj Mohanty, Ryan Oblak, Sadaf Tajik, Sagar Tewari, Sean McLaughlin, Shinya Yoshida, Shubham Raj, Sidney Monteiro, Stefan Heule, Steph Dietzel, Stuart Pernsteiner, Suzanne Millstein, Tony Wang, Trask Stalnaker, Travis Haagen, Utsav Oza, Vatsal Sura, Vlastimil Dort, Weitian Xing, Werner Dietl, Zhiping Cai. In addition, too many users to list have provided valuable feedback, which has improved the toolset's design and implementation. Thanks for your help!

35.7 License

Two different licenses apply to different parts of the Checker Framework.

- The Checker Framework itself is licensed under the GNU General Public License (GPL), version 2, with the classpath exception. The GPL is the same license that OpenJDK is licensed under. Just as compiling your code with `javac` does not infect your code with the GPL, type-checking your code with the Checker Framework does not infect your code with the GPL. Running the Checker Framework during development has no effect on your intellectual property or licensing. If you want to ship the Checker Framework as part of your product, then your product must be licensed under the GPL.
- The more permissive MIT License applies to code that you might want to include in your own program, such as the annotations and run-time utility classes.

For details, see file `LICENSE.txt`.
